Notation.—The patient was greatly debilitated and emaciated. The breast was small and indurated. Removal of the breast was rapid and painless. Skin grafting was done at the end of the second week. Three weeks from the beginning of the operation the patient was discharged. No axillary glands were palpable. The case was referred to me for the chemical operation by her physician. Mrs. R., who lives in the South, reports herself perfectly well; new skin surface soft, smooth, flexible, and functionating; no arm stiffness; general health improving.—January 15, 1916.

Case V.—Mrs. G., age 57, widow. Admitted August 12, 1915. Ad. No. 22450. Chief complaint, tumor of breast. Five years ago noticed a small lump, the size of a marble, in right breast. Not much growth was noticed for the first two years. A short time later, the skin became discolored; no discharge from nipple. Never had any pain from breast. The mass continued to grow, and about eight months ago the skin broke down over the tumor. Menopause, ten years ago. No injury to the breast; no complications during the nursing period; no other case of cancer in the family. *General appearance:* Large, stout, florid woman. Surgical condition.—There is a large bleeding mass, a little larger than an egg, in the upper portion of the right breast. It involves the nipple and is firmly adherent to the chest wall. There are no palpable axillary or supraclavicular nodes. The left breast is the seat of a transverse scirrhus cancer. There is a slight induration of a portion of the scar,—it passes through the nipple. Scar is from an ancient traumatism. Axilla, negative. X-ray of chest, taken September 21, shows

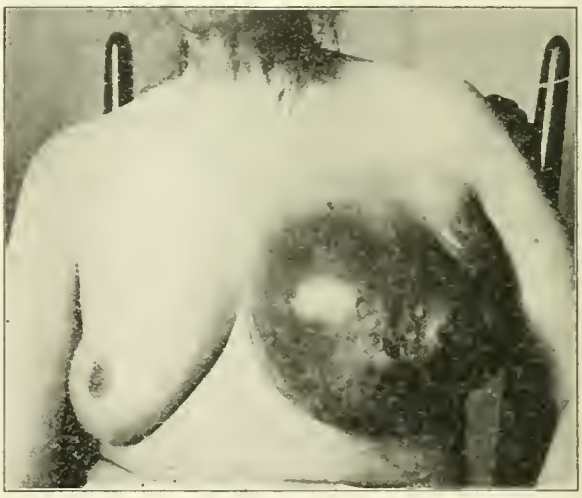

Fig. 2.—Case VI. Inoperable carcinoma of the breast in a woman aged 47 years.

probable metastases to both lungs. General condition, fair.

Chemical operation begun August 30. Both breasts were removed. Fine recovery. Skin grafting was done September 18. Temperature fluctuations between normal and 102.8°; respiration between normal and 26; pulse between normal and 101. Pathological report, alveolar carcinoma.

Notation.—This patient's general condition was very good. Notwithstanding both breasts were removed, there were no complications. The nursing was excellent. The active agent being kept wholly within bounds, there was no pain. The breasts, together with a half-inch layer of pectoral muscle and a large right pectoral gland, were removed. The patient was discharged four weeks from the beginning of the chemical operation; no palpable axillary glands. Last report: patient perfectly well; has gained fifteen pounds in weight. X-ray of chest, taken February 3, 1916, still shows probable metastases to both lungs.

Case VI.—Mrs. T., age 47, married. Nursed her children. Admitted October 22, 1915. General history, negative. Chief complication, large ulcerating tumor of the left breast. Four and a half years ago, noticed small lump in breast, gradually increasing. Shooting pains for last six months. Systolic bruit all over chest.

Description of tumor: The left breast is immensely enlarged. (See Fig. 2.) On the outer surface, are irregular ulcerations that are sloughing. The general color is purple, the surface is irregular, due to separate bosses fixed to underlying tissue. Foul discharge from ulcerations. Tumor surface, irregular in contour. Skin is smooth and shiny. There are large (glandular) masses extending toward the axilla. The induration extends upward to the clavicle, outward to the mid-axillary line, and internally to the costal margin. Parallel (or nearly so) to left clavicle, is a varix-multiple enlarged vein. Ulcerations are in region of nipple. These have sloughing bases and foul discharge. Tumor is fixed to the skin above and to the chest wall beneath, is non-sensitive, and very vascular. Approximate measurements of tumor mass are 7 x 7 x 3 inches. Pathological report, from tissue from edge of ulceration.—Large alveolar carcinoma, somewhat resembling adenoma malignum. General hemorrhagic pigmentation (Ewing). X-ray of chest taken October 25, 1915, shows diffuse shadow of a very large mass over the right side of the chest which obliterates all detail at the hilum of the lung on that side (Holding).

Operated upon by chemical method on October 29, 1915. On account of the extreme vascularity and magnitude of the growth, progress was slow. Skin grafting was done January 30, 1916. Temperature fluctuations ranged between normal and 102°; pulse between normal and 120; respirations between normal and 26.

FIG. 3.—Result of the chemical operation and skin grafting in the case of mammary carcinoma in Fig. 2.

This patient seems perfectly well and does her usual housework.

The two following case reports are from the West Side German Dispensary-Hospital, where the operations were performed:

CASE VII.—Mrs. J. S., married, age 64. Admitted June 4, 1915. Multipara; menopause passed at age 45; mother died of carcinoma of stomach. Three months ago, first noticed a "lump" in the outer part of the right breast. This was at first neither tender nor painful. The tumor grew rapidly, at the same time becoming painful. The breast was greatly enlarged; the outer half being distorted and irregular in outline from the presence of an indurated mass which was adherent to both under- and overlying fascia. The skin, also adherent to the tumor, was unbroken, smooth, and tense; the nipple was sunken below the general level. There were no ulcerations. Axillary glands indicated metastasis, there being a lymph node, the size of a robin's egg, under the edge of the pectoralis major muscle, and smaller ones near the vessels. Clinical diagnosis, carcinoma. Pathological diagnosis, adeno-carcinoma. No Roentgenogram of chest taken.

Operation by the chemical technique, June 5, 1916. The entire breast, a half inch in thickness of the pectoral muscle, and the enlarged pectoral node were removed. Skin grafting was done June 20. The patient was discharged about four weeks from admission. The axillary glands had subsided so that they were scarcely appreciable.

Notation.—Examination of the patient, June 15, 1916, shows the chest wall smooth; skin soft, movable, and freely functionating. Slightly enlarged fibrous glands in dome of axilla. No restrictions of arm movement other than she has had for several years, from an old dislocation. The patient was doing her housework, and declares herself perfectly well. She has gained twelve pounds in weight, and is the picture of healthy old age.

CASE VIII.—Mrs. D. A., age 66, married forty-one years. Admitted October 31, 1915. Had two children, nursed but one; always in good health; weight, 210 pounds. Menopause began at forty-eight and ceased at fifty-two years. First noticed a hardening of the right breast in the vicinity of the nipple in June, 1915. Growth was quite rapid. There has been no pain, but an occasional "stitch" runs through it. The right breast is very greatly enlarged and distorted by the presence of a growth the size of a large orange. This growth is of irregular contour, hard, non-sensitive, adherent to the fascia below and the skin above. The mass occupies almost the entire breast, but mainly the upper outer quadrant. The nipple was deeply depressed, ulcerated, and discharged a foul exudate. The axillary glands were enlarged, but not greatly so. A large pectoral node at the outer edge of the great pectoral muscle presented, the size of a medium horse-chestnut. There was also a large supraclavicular node, rather painful to pressure and of the size of a large hazelnut. The arm was somewhat swollen and at times painful. The surrounding skin was dotted with brownish, flattened papules, ovoid in shape, and covering the upper half of the body above the umbilicus and mid-axillary line laterally. Pathological report, fibro-carcinoma (Ewing).

Operation by chemical method was begun October 1, 1915. On account of the great size of the breast, the removal occupied time in proportion. All the skin layers and the fascia or capsule of the breast were removed with caustic potash under primary anesthesia, and the zinc compound was applied. Skin grafting was done in the third week, the grafts all taking. The patient was discharged December 1, 1915. No *x*-ray examination of chest was made.

Notation.—This patient was seen July 1, 1916, at which time the breast area was level with the chest, covered with soft, movable, functionating skin transplants. The feeling of constriction of the chest was lessening. The arm was greatly swollen, while the nodes in the axilla were still perceptible. The supraclavicular node was also still palpable. The patient's general health was improving, and she felt well.

Mrs. A.'s condition was absolutely inoperable when she consulted me. Surgical relief had been denied her by other surgeons. The operation was done as a palliative measure, since internal metastasis was quite probable, as indicated by her general condition.

17 EAST THIRTY-EIGHTH STREET.

EPIDEMIOLOGY AND PREPAREDNESS.

BY CHARLES E. NORTH, M.D.,

NEW YORK.

WAR, earthquake, fire and pestilence are more stimulating to the public mind than any other kind of events. The consciousness of the civic body is aroused to a realization of the common interest and the necessity for self-preservation by the common danger. An epidemic of infectious disease is like a conflagration in that it starts from a small beginning, and if unchecked may spread like a fire through a municipality or state.

Through the centuries, time after time, epidemics have swept through human communities, but in spite of their frequent occurrence and the temporary panics caused thereby, there remains a strange lack of preparedness, and each epidemic seems to catch the community it attacks unprepared. Recently the mayor of one city remarked to the writer: "Cities must have epidemics once in a while, and the only way is to let them burn themselves out." Thus the epidemic is still in most minds a periodic dispensation of Providence which suffering humanity must accept. The chronic indifference of the community to its own self-preservation has prevented the development of the science of epidemiology and of expert specialists able to qualify as epidemiologists. While it is true that there is an abundant supply of bacteriologists, chemists, pathologists, physicians, sanitary inspectors, and other specialists, yet at times of epidemic it is difficult to discover men of ripe experience in the control of epidemics who can qualify as specialists in epidemiology. Experience with more than one epidemic as a qualification would reduce by one-half any group of experts called in for consulting purposes, and, perhaps, eliminate the health officer himself. More than two epidemics' experience would reduce the expert list another 25 per cent., and three or more epidemics would probably reduce the list to one man. Such is the limitation of expert practice in this special science. In America it is doubtful whether there are more than one-half dozen men who can personally qualify as experts in the science of epidemiology. As a consequence, the majority of epidemics are handled by inexperienced persons, and the death rate and morbidity rate are correspondingly higher than they would be if standard methods in the control of epidemics in every community were immediately applied.

Epidemiology is not bacteriology. It is not chemistry, or physics, or medicine, or pathology. It is not vital statistics, or sanitary science, or any of the special branches of medical or public health knowledge. It is a science of sciences. It partakes of all of the other branches of medical and public health work. Epidemiology is an overhead science, in which the other sciences are used as instruments. It co-ordinates not only the knowledge secured through the special medical and sanitary sciences, but it plays upon them as upon an instrument, laying the emphasis when necessary on the one hand or on the other, as the particular problem to be solved demands.

For this reason the chemist, the bacteriologist, and the other specialists in the various special sciences are not necessarily epidemiologists. The specialist with his nearby point of view may not have the comprehensive view necessary to play the part of a good epidemiologist. The first essential of a good epidemiologist is a point of view which is remote and detached so that he can view the field from a sufficient elevation to give values which are not distorted to the various facts and data collected. The epidemiologist must not overestimate or underestimate the value of the facts brought to him. His view, in short, must be macroscopic, rather than microscopic.

The science of epidemiology itself is so new that even a definition has not been formulated. It deals primarily with the investigation and control of epidemics of infectious diseases. Such epidemics can be divided into two great classes. The first includes the annual or seasonal epidemics, such as infant diarrhea and dysentery in the summer; typhoid fever in the fall; grippe, bronchitis, and pneumonia in the winter, and scarlet fever, whooping cough, chickenpox, measles, etc., in the spring. These annual waves of infectious diseases sweep through all communities with clocklike regularity each year.

The second class are those which visit communities at irregular intervals and unexpectedly, including smallpox, cerebrospinal meningitis, typhoid fever, septic sore throat, infantile paralysis, plague, etc. Strange to say, the annual or seasonal epidemics are accepted as a matter of course and looked upon by many health officers as unavoidable. While the death rate from the seasonal epidemics is far greater than from the irregular epidemics, yet the irregular epidemic is sufficiently unexpected to be dramatic and to cause a much greater sensation in the community mind.

Though the science of epidemiology is new, medical literature and public health records furnish abundant material for the establishment of certain definite principles of action. While the collection of data is still incomplete, and some infectious diseases are not fully understood, yet many of the principles are sufficiently clear to make it possible for the student of epidemiology to recognize the action which communities must take to put themselves in a state of preparedness.

The work of Bentham, Chadwick, and Southwood Smith from 1833 to 1848 resulted in a recognition of the necessity of a centralized control by public officials over sanitary conditions, so that the state became a party to the health of the individual. The Chadwick agitation brought about the establishment of a central statistical department in London, known as the Central Register's Office, and the history of registration of cases of disease dates from this time. This registration was the basis of the elementary sanitary laws established for London, and eventually for other parts of England. Since 1875 three fundamental principles of public health control have been recognized in England. Notification, meaning the reporting of cases to municipal health authorities, was applied to London and adopted by over eleven hundred provincial districts. This notification is interesting because the law provides that, "Diseases must be reported by any one of seven persons, the duty falling in the following order: The head of the family, the nearest relative in the building, the person in charge of the patient, the occupiers of the house, the attending physician, and the assistant attending physician. A notice by any one of these relieves those who come later in the list, but not those who come earlier. Penalty for failure to report is forty shillings."

A second provision in the early English law is that, "Whenever any part of England or Ireland appears to be threatened with an epidemic, the local government board may make regulations for guarding against the spread of the disease within the whole or any part of the district of any local authorities." This fixes supreme power with supreme authority in the case of emergency.

A third important principle established by this law is that it prohibits "illegal exposure of an infected person without proper precautions against the spread of said disorder in any street, public shop, public conveyance, etc." This refers to walking cases of infectious diseases, and establishes control over such persons by public health authorities.

The demonstrations of Pasteur and Koch threw

great light on the direction which must be taken by the science of epidemiology. For many years after bacteria were demonstrated to be the cause of infectious diseases there existed a widespread belief that germs could live out of doors for considerable lengths of time, and that dirt, garbage, air, dust, rags, clothing, streets, walls, and floors were the common means for the transmission of infectious disease. In short, external agencies were believed to be the means for carrying disease from person to person. This meant the environment of human beings rather than the human beings themselves.

As a consequence, sanitation was looked upon as the most important weapon for the control of epidemics, and sanitary science, dealing with the destruction and prevention of external infections, was developed as a special department of knowledge treating with the proper cleaning up of this environment. The cleaning of streets, the disposal of garbage, the disposal of sewage, the purification of water supplies, the disinfection of dwellings, pasteurization of milk, have all been developed as a result of this era of sanitation. Faith in sanitation is so widespread that it still remains the chief weapon in the hands of public health authorities, and a "clean-up" campaign is the first measure to be applied in times of epidemic diseases.

A more intimate study of the nature of infectious disease has brought about startling revelations during the past ten years and has created a new and powerful influence which marks a distinctly new era in the methods for the control of epidemics. This may be called "the era of contact infection" as contrasted with the older "era of sanitation." Contact infection recognizes the bacteria of disease as primarily parasites of warm-blooded animals, unable to live for any great length of time outside of living bodies. It recognizes that occasionally the environment may be responsible for the transference of infection, but that most of the time infection is transferred directly from person to person by contact.

The discovery that persons in apparently perfect health may be the carriers of infectious bacteria of a number of well-known infectious diseases has entirely changed our point of view regarding the prevention of these diseases. Not only carriers, but mild cases and missed cases are now known to be the means of spreading infection. The picture of an epidemic has been changed from that of a series of sick persons, transferring disease through external things, to a picture of sick persons, each of whom is surrounded by a group of those with whom they have come into contact, and this group of contacts is now recognized as the chief source of danger to the community. It is out of this group of contacts which surrounds each recognized case that the next crop of cases may be expected. The transference of infection frequently occurs before disease is recognized. Thus each case becomes a focus and the center of a small, localized epidemic all its own.

In the year 1916, however, the health authorities even of our largest cities still cling to sanitation as their most important weapon, and make the control over carriers, mild cases, missed cases, and persons who have come into contact with the recognized cases a secondary and incidental matter. This fact justifies us in attempting to weigh the merits of this new principle of control by a brief survey of the opinions of leading investigators of this subject.

Chapin, in his epoch-making book entitled "Sources and Modes of Infection,"[2] gave a powerful impetus to the recognition of infection by contact. He states that "Municipal cleansing is of little use in the prevention of disease. Mild, atypical cases and unrecognized cases of infectious diseases are often extremely common. . . . They may be more numerous than recognized cases. . . . Any scheme of prevention which fails to take into account carriers and missed cases is doomed to partial and perhaps complete failure. I have sometimes been told that I lay too much emphasis on contact infection, but if it is the principal way in which disease spreads, too much emphasis cannot be placed upon it, and it seems to me that the evidence is that it is the chief mode of infection."

Doty,[3] in his book entitled "The Prevention of Infectious Diseases," says: "The popular fomites theory is unsupported. Fomites are not the cause of disease, but persons, insects, food, and drink. . . . The control of disease consists in an investigation to discover the whereabouts of those who are infected and to secure their strict isolation. Also, to detain, or in some manner keep under observation, those who have been exposed to infection and who are known as 'suspects,' and to detect irregular and unrecognized cases which are largely responsible for the outbreaks of infectious diseases."

Wassermann[4] says: "In practically all infectious diseases the existence of persons has been established in the surroundings of all cases who are apparently perfectly well, but are, nevertheless, the carriers of the corresponding germs. These, because they go about at will, become a source of further distribution of the epidemic."

Rosenau[5] says: "The practical value of isolation varies with each disease . . . with the existence of latent infections, missed cases, carriers and other factors which influence the spread of the infection."

Kirchner[6] says: "The basis for the control of epidemics in war time and in peace consists in the determination of the cases themselves as well as in the establishment of germ carriers from those surrounding the patient. At the outset of an epidemic it is necessary to ascertain how many apparently healthy individuals in the patient's surroundings harbor disease germs."

Kiefer[7] says: "The first necessary step in the control of epidemics is a campaign of education to teach the public something about contact infection."

Neufeld[8] says: "The modern fight against epidemics consists in the rapid, accurate discovery not only of the patients, but also of all persons capable of transmitting the disease germ. Experience has repeatedly shown that excellent results were obtained when undoubtedly only a portion of the disease transmitters have been checked."

Hune[9] says: "The number of healthy germ carriers is small at a time free from epidemics, in the beginning as well as at the end of epidemics, but it is enormously high at the height of the epidemics. For this reason early measures alone are appropriate and practicable."

MacNutt,[10] in a review of epidemiology, says: "Carriers, missed cases, and incipient cases have within a few years been shown greatly to aggravate problems of control and to add an entirely new chapter to epidemiology, revolutionizing our views in important respects. A study of every epidemic should include a careful consideration of the activity of this class of cases."

The pendulum has swung too far in favor of

sanitation, and it is now, after many years, swinging back again to contact as the chief means of the transmission of infectious diseases. The word "contagion" in its original means contact, and contagious diseases have been called such because in the earliest times it was believed that they were transmitted by contact. We have been mistaken in getting too far away from this idea, and we are now getting back on to solid ground and a full recognition of the vital importance of contact, not only on the part of severe cases, but on the part of carriers, mild cases, and unrecognized cases, as the chief means of transmitting the majority of infectious diseases.

It is possible to draw up a list of the measures which experience has shown are effective in the suppression of epidemics, as follows:

General Measures	*Special Measures*
Legal powers	Water purification
Notification	Pasteurization
Inspection and diagnosis	Destruction of animals
Registration	Destruction of insects
Field investigations	Vaccination
Tabulation	Serum therapy
Medical treatment and nursing	Diphtheria antitoxin
Isolation	Nose and throat disinfection
Hospitalization	Disinfection of discharges
Quarantine	Personal hygiene
Sanitation	
Control of contacts	
Disinfection	
Education	

Each measure in the list is capable of special modification to meet the conditions created by a special epidemic. The selection of the correct measure and its application to the community at the right time and in the right place requires of the epidemiologist not only a familiarity with the special epidemiology of the disease he is combating, but a peculiar intuition which can be obtained only from experience.

The application of the science of epidemiology to American municipalities has been inefficient for a number of reasons. The majority of communities have not yet elevated the health department to a position of sufficient importance. Even where financial appropriations are considerable, there is commonly a tendency to look upon public health service as a political matter. Frequent changes of health officers and appointments to such positions of men with no particular qualifications other than political qualifications, or with no experience, means lack of preparedness.

Real students of the science of epidemiology are so scarce that standard methods for handling epidemics are not fully recognized. As an illustration of this uncertainty, one American author says that "In America, when the number of cases of measles amounts to one in one thousand of population, there is an epidemic. In England, measles is epidemic when there are 1.2 per thousand. In New Orleans, measles is epidemic when there are between 2000 and 5000 cases, or 22 per thousand population; and, mark you, any disease is epidemic when there are ten cases in close proximity to each other." Another prominent health authority administers comfort to the inhabitants of his community by comparing the number of cases of epidemic disease with the total population, and showing how infinitely small the percentage really is. It is a question whether such arithmetic conveys any real comfort to that portion of the population living in the afflicted locality. The addition of large groups of healthy persons to vital statistics is hardly an adequate means for offsetting the seriousness of an outbreak in a limited locality.

In America seasonal epidemics are too largely accepted as a matter of course, and no such thing as preparedness is undertaken. In the fall the annual typhoid epidemic is a distinct surprise. The grippe epidemic in January is always unexpected. Scarlet fever and measles in the spring is a startling novelty. Yet such a thing as preparing this year for the epidemics of next year is unheard of, because these surprises are chronic.

I will mention for illustration one thing which is not done, but which might be done to reduce the annual number of cases and deaths from infectious disease. Assume a class of thirty school children. One of them contracts measles and is sent home. Two weeks later fifteen others in the class come down with a rash and are sick with measles, to the great surprise of their parents, who were not notified by the school authorities or by the health department that their children had been exposed. Two weeks later in the homes of the fifteen children, among their brothers and sisters, and in the neighboring homes among playmates, over one hundred cases of measles are discovered. Here we have a third crop of measles cases entirely due to a needless exposure, because the parents were not notified, either by school authorities or health authorities that such exposures had taken place. Only a little notification to parents and only a little education regarding the meaning of contact would have prevented this third, and largest, crop of cases. Many parents are sufficiently intelligent to understand the importance of keeping exposed children separate from unexposed children. The condition cited above is not imaginary, but really exists to-day in all American cities not only in regard to measles, but scarlet fever, whooping cough, chicken-pox, mumps, and all the infectious diseases of childhood contracted in the public schools. The neglect of school authorities and health authorities to inform parents of the exposure of children to these diseases, and to point out the value of isolation for the protection of other unexposed children is directly responsible for three-quarters, and perhaps a higher percentage, of the cases of infectious disease among children.

Proper preparedness for the occasional and irregular epidemics which occur is also lacking. There is no such thing as a first-class bureau of epidemiology in America. No municipality employs a specialist in epidemiology, qualified by experience to take active control of epidemics. Municipalities depend for their protection on such incidental experience and incidental organization as their health department may possess. It is small wonder, in view of the circumstances, that epidemics, whether seasonal or irregular, catch municipal health departments napping, and almost panic stricken.

New York City illustrates by its own career instance after instance of this sort of unpreparedness. A review of the epidemics from which the city has suffered shows the imperfection of methods of investigation and control. Where the department of health has not entirely missed the discovery of the true cause of an epidemic, the outbreaks recorded have pursued their course uninterrupted, and in some instances for weeks, and even months, unannounced. A health department which in other respects is excellent has been peculiarly weak in its control of epidemics.

As an illustration of this deficiency may be mentioned the current epidemic of infantile paralysis. The records show that from April 13 until the last

day of May, 1916, there were only nine cases of infantile paralysis in the greater city, but from June 6 to 10 there suddenly appeared ten new cases. From June 10 to 15 nine more appeared, making nineteen cases in nine days. From that time on the epidemic increased by leaps and bounds, and still continues. The record up to this writing, tabulated below, shows 3098 cases and 647 deaths.

Date	*Cases*	
April 13 to June 1	9	
June 2 to 10	10	
June 11 to 15	19	(epidemic evident)
June 16 to 20	35	
June 21 to 25	121	
June 26 to 30	279	
July 1 to 4	463	
July 5 to 10	1,082	
July 11 to 17	2,124	(control of contacts)
July 18 to 20	2,446	
July 21 to 26	3,098	

The New York City Department of Health undertook emergency measures to suppress this epidemic the first week in July. It laid emphasis on the cleaning of streets, disposal of garbage, and sanitation. The reporting of cases and the isolation of discovered cases seems to have been carried out so far as possible. But a most remarkable omission was the failure of the Department to take any steps for the control of contact cases until July 14. On that date, the special committee appointed by the mayor passed a resolution stating that "It would be wise to follow the ramifications of personal contact radiating from every known case of infantile paralysis so far as possible." And this work was supported by the contribution of $50,000 from a well-known foundation to be expended under a specialist, who opened his office in Brooklyn on the 17th of July, and with a force of physicians and nurses undertook to follow the cases of persons who had come into contact with this disease. If control of contacts was good practice on July 17, it would have been even better practice on June 15.

Infantile paralysis is a disease in which contact infection is the only known means of transmission. In support of this, Flexner[11] says: "The virus enters the body, as a rule, by way of the mucous membrane of the nose and throat, and is readily distributed by coughing, sneezing, kissing, and by means of fingers and articles contaminated with these secretions. * * * The fact has been determined that the noses and throats of healthy persons who have been in intimate contact with cases of infantile paralysis may become contaminated with the virus, and that such contaminated persons, without feeling ill themselves, may convey the infection to other persons, chiefly children, who develop the disease. * * * Protection to the public can best be secured through the discovery and isolation of those ill with the disease and the sanitary control of those persons who have been associated with the sick."

The MEDICAL RECORD of July 8 stated: "A more plausible theory than that of the biting of the fly is that the disease is spread in the same way as influenza or common colds, for it is known that the pathogenic agent is contained in the nasal secretions of the sick."

The *Journal of the American Medical Association*, in its issue of July 8, states editorially regarding the epidemic in California in 1913: "In practically every instance infection could be explained on the theory that epidemic poliomyelitis is transmitted by contact from acute cases or carriers. * * * All become potential agents for the dissemination of the virus, as do also healthy persons who have been in intimate contact with those who are ill. The prevention of such dissemination is the actual prevention of the disease."

Neufeld[12] says: "The infected virus exists not only in the patients having the disease, but also in acute cases for at least six months after, as well as in healthy persons in the surroundings of the sick."

The quotations are sufficient to make it clear that the best knowledge regarding infantile paralysis is that transmission commonly occurs by contact, consequently the epidemiologist in taking steps for the prevention of this disease must look upon the control of all persons coming in contact with the cases of this disease, not as an incidental measure, but as the most important measure which can be applied for the suppression of such epidemics. The delay in applying this measure for the suppression of the New York City epidemic is an instance of the character of the control of epidemics so commonly applied in American municipalities. True preparedness would have made it possible to apply the right remedy at the earliest moment when the outbreak was recognized.

The warfare against infectious diseases requires a preparedness all its own. It is necessary to maintain an emergency form of organization just as a fire department is organized. There must be not only a perfect alarm system, but a force capable of quick and intelligent action in the location where the conflagration starts. The ordinary type of bureau of infectious diseases cannot answer this purpose. It demands a special bureau of epidemiology, with a man at its head who has specialized in that science, and with a consulting board, making available to him, instantly and regularly, the best consulting service. Such an organization might well be included within the regular department of health; but so connected with the various special departments, such as the diagnostic laboratory, statistician, research laboratories, sanitary inspection service, disinfection service, etc., that all of these departments can be instantly swung into line, not aimlessly, but as instruments in the hands of the epidemiologist. In his book on typhoid fever, Whipple says: "To control an epidemic and keep it within bounds demands prompt and energetic measures. A community afflicted with an epidemic is sometimes almost panic stricken. Correspondents fill the public press with theories, and many foolish things may be said and done. What is needed is a strong central authority that for a time can exercise almost autocratic power, and a government and a public opinion that will uphold such authority and provide all necessary resources." Like the fire department, a real, strong bureau of epidemiology might seem to be inactive between epidemics, but when one estimates the cost to the community of such conflagrations of disease as occur, it will appear that like the fire department, communities are justified in keeping mobilized constantly an adequate force, properly informed and equipped, and capable of acting intelligently and with a strong hand to instantly suppress a conflagration of disease.

True preparedness means that steps be taken now for the epidemics that are to occur in the future. Steps should be taken now for the grippe epidemic that is to occur next January. Steps should be taken now to prevent the scarlet fever epidemic that is due next spring, also the measles, whooping cough and other spring outbreaks.

It is certain that the regular seasonal epidemics

will yield to a campaign of preparedness. Public education alone can be made to do wonders in the reduction of mortality and morbidity in these seasonal outbreaks. For the occasional and irregular outbreaks preparedness also can give the community a far better service than it has ever received in the past. The immediate application at the beginning of an outbreak of the very best measures for the suppression of the epidemic would result from an adequate study of each of the infectious diseases causing these irregular outbreaks and a comprehensive plan of action readymade for immediate application when emergency calls.

Where communities are not big enough to maintain a department of epidemiology of the first class, such service should be established for the district or county. Certainly each state should have a first-class department of epidemiology, fully equipped to suppress epidemics that occur within the State. Above all, the United States Public Health Service should have a national department of epidemiology so thoroughly competent that it can act in interstate outbreaks, and, when called upon, in local outbreaks.

It is looking ahead considerably to assume that communities are yet ready to accept public health service of this kind. It will probably be necessary for each large municipality to have several severe epidemics of its own to arouse the civic consciousness. New York City should take the lead in such preparedness. In this particular instance the suffering which has occurred can be made of actual benefit to the city if it results in immediate steps for a stronger form of organization and adequate preparedness for the prevention of the epidemics of infectious diseases which experience has shown are certain to threaten the city in the future.

VACCINES IN ACUTE INFECTION.

By ELLIS BONIME, M.D.,

NEW YORK.

ADJ. PROFESSOR IMMUNOTHERAPY DIVISION OF SURGICAL DEPARTMENT, NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL.

It is not the purpose of this paper to enlarge upon the method of using vaccines in acute disease, but rather to bring out five important points which are essential to make the use of vaccines in acute infections successful.

It is well known that the failure of vaccine has been reported most frequently in acute infections and if we can find a way to better success in these cases, we shall come nearer to saving life than in any other form of disease coming under the therapeusis of vaccine.

Acute infection counts within its radius the most desperate conditions; and because of failure we have acquired a fear of the use of vaccines,—a fear largely brought about by the idea that vaccines add to the toxins already present in the body. I do not wish to go into the theories of vaccine therapy in this paper so as to avoid befogging the importance of the points I wish to bring out. I shall not go into a detailed explanation why the above fear is groundless and the reason for it entirely without foundation. I shall merely state that vaccines are not toxins; that they merely stimulate at the point of inoculation the formation of antibodies specific to the vaccine and therefore to the disease.

The five important points that I wish to bring out in this paper are as follows: (1) A correct etiological, bacteriological diagnosis; (2) the correct time of administration of the vaccine; (3) the determination of correct intervals between inoculations; (4) the prevention of the growth of the causative organism, or the growth of new organisms beyond the reach of the antibodies; (5) the proper preparation of vaccines from growths of the causative organism.

I. *A correct etiological bacteriological diagnosis.*—In discussing the correct etiological, bacteriological diagnosis, we must bear in mind that a virulent bacteria will very often grow much more rapidly on artificial culture media than virulent ones, and if both are put on the same culture medium will destroy the virulent bacteria. Thus it can easily be seen how a vaccine may be made from an unrelated organism. The failure to get results in the use of immunotherapy has often been brought about by the use of just such a vaccine. The taking of a smear from the point of infection, inoculating culture tubes, and sending them to a laboratory with a request to make a vaccine, without first determining the causative organism, will bring about many failures without vaccine as a therapeutic agent being at fault. I have seen containers filled with vaccine, ready for shipment to a physician, labeled "so many million organisms per cubic centimeter, containing a small micrococcus, a bacillus unidentified, and *Staphylococcus albus*." This vaccine may or may not have contained the causative organism, and not only is the presence of the causative organism in doubt, but its quantity unknown, a fact which prevents even approximate dosage.

To illustrate this point, I shall relate the following case:

Case I.—Miss W. H., aged 28. Operated on by suprapubic cystotomy for severe hemorrhage into the bladder from tuberculous ulcerations in the bladder wall. Three or four days later a severe chill occurred, followed by temperature rise to 104° or 105°, and for 93 days this daily temperature rise continued, with remissions to below normal. The patient's condition at this time became very grave. She was greatly emaciated. About the ninetieth day, tubercle bacilli were found in her urine and for the first time the tuberculous origin of the trouble was discovered. This discovery was responsible for my being called in on the case by the attending physician, who knew my work with tuberculin. The question of vaccine had not been considered up to this time. As previously stated, acute infection had now lasted for ninety-three days, and when I examined her, I found her in a most desperate condition, suffering from what appeared to me to be a streptococcus septicemia. All urine came from the suprapubic incision, but was not recognizable as urine; it was a thick, creamy discharge having microscopically the appearance of pure pus which on analysis showed urinary elements. A microscopical examination showed numerous tubercle bacilli with a short-chain small streptococcus predominating, with an admixture of other organisms

such as staphylococcus, and a small micrococcus, the identification of which we did not deem worth while at the time. Suitable culture media were at once inoculated and the making of a vaccine of the streptococcus was ordered. Meantime a stock streptococcus from a similar condition was at once injected in order not to lose valuable time waiting for the autogenous vaccine to be made. The laboratory report, both a day and two days later came back that no streptococcus grew in the media. For a few days fresh inoculations were made with the same result. Finally, on the third or fourth inoculation, we were able to isolate the streptococcus. The reports always came back that there grew either a small micrococcus unidentified, a staphylococcus, or the colon bacillus; and in each case I rejected the growth for a vaccine, as I was convinced from the pus appearance in the smear that the streptococcus was the causative organism. The stock vaccine proved efficient; we not only had the patient's temperature normal within 48 hours after the first inoculation, but after three more inoculations, during a period of two weeks, the patient was out of bed. Pure urine appeared from the suprapubic wound with only a microscopic trace of pus. At this writing the patient is still coming to the office for tuberculin treatment, which was instituted ten days after the first inoculation of vaccine; the suprapubic wound is closed; the urine which began to come through the normal channel shortly after the pus disappeared, is free from tubercle bacilli; the bladder is under normal control, micturition occurring only four or five times a day and once at night; her weight, which was ninety pounds at the beginning of treatment, is now 116, and she has for the last two weeks resumed her former occupation of general housework.

2. *The correct time of administration of the vaccine.*—In discussing the time of day for a vaccine inoculation in acute infection, we must bear in mind that time is a great factor in this class of patients. We cannot indiscriminately give an approximate dose of vaccine, especially if we are forced to use a stock vaccine pending the manufacture of an autogenous one, and then wait four or five days for an effect before a repetition of the dose. We must so gauge our inoculation, that in 24 hours we may be able to judge whether our inoculation was sufficient to effect a beneficial influence on the patient's condition.

In studying a temperature curve, in acute infection, we find that during 24 hours there is an ascent of temperature continuing for several hours, a period during which the highest temperature is maintained, and then a long interval during which the curve descends, reaching its lowest level at normal, or even below normal. The period of ascent is the period of resistance, during which time the defensive mechanism of the patient is exercised to its maximum. At the height of the curve the patient holds his resistance until the moment of exhaustion, when the temperature begins to fall. During the falling of the temperature there is a multiplication of the bacterial elements, replacing those destroyed during the defense and perhaps even accumulating to a larger extent than they were present before. It is during this period of lack of defensive power on the part of the individual, plus the lowered temperature which is favorable to the growth of bacteria, that we can extend any aid by artificial means. The establishment of an antibody factory in the subcutaneous connective tissue, away from the point of infection, will prevent the reinforcement of the enemy and will turn the tide of battle in favor of the patient. It is therefore clear that a vaccine inoculation should be given during the descent of the curve; at the same time we must allow the maximum time for the accumulation of a sufficient amount of artificially stimulated antibodies to produce a positive effect. And so it is best to choose an hour or two after the high point of temperature for the day has been reached. This will allow sufficient time for the vaccine to become active before the lower temperature of the day has been reached; in other words, the time of the least resistance; and if the dose was sufficient, this effect will be shown by the high point of the day following not reaching as great a height as on the day previous. If the height of the day is 104° and is reached about 4 P. M., the proper time for inoculation would be approximately 6 P. M., and the efficacy of this dose should be manifested by the temperature at 4 P. M. the following day reaching only between 102° and 103°. However, if no temperature change occurs in twenty-four hours, then the dose given was not sufficient and a reinoculation can be practised in the same relation to the height of the temperature as previously.

Thus it is clear that by gauging inoculations at the correct time with relation to the height of the temperature curve, we can judge the effect of treatment within twenty-four hours and reinoculations will be practised without the loss of precious time. At these reinoculations, either the dose can be increased, or the discharge further examined for a possible error in the stock vaccine used; or one can become convinced that an antogenous vaccine is necessary without unnecessary delay.

To illustrate this the following case may prove of interest:

Case II.—Mrs. M. R., aged 66, had suffered from diabetes and chronic interstitial nephritis for many years, but managed to keep in fairly comfortable health by being under the care of physicians at all times. She infected her great toe in cutting a corn; the infection spread rapidly over the entire leg with swelling doubling its size, temperature rose to 104° and the surface of the entire limb looked almost like an erysipelas. Both from the appearance of the leg (erysipelas) and the septic temperature I concluded that it must be a streptococcus infection and used as stock an erysipelas strain from a former patient. The temperature reached its height at about 9 P. M., and when I arrived between 10 and 11 P. M. to give the first inoculation, I found the patient in her fifth day of the disease, with the last two days in a very critical condition, having been constantly in a muttering delirium. The pulse was very poor and the urine showed signs of acute nephritis.

A dose of 20 mil. of the vaccine was administered, but the temperature at 9 P. M. the following day reached 104.5°. At 11 P. M. 40 mil. of the streptococcus was given, a smear from the serum taken from a bleb over the ankle showed a few short chains of streptococci; cultures were made from this, and a vaccine ordered, but was cancelled two days later, as the temperature in twenty-four hours after the second inoculation had reached only 102.5°, with the patient out of delirium, and expressing a desire for food. The swelling markedly diminished, the redness almost entirely disappearing except for four or five patches about the size of a silver dollar remaining over both sides of the ankle, two or three over the anterior surface of the tibia, and one just over the knee. Two days later a fluctuation appeared under these red spots; under local anesthesia punctures were made and a seropurulent discharge evacuated from each area. Cultures produced no growths from this discharge. Forty-eight hours after the last inoculation the temperature came to normal and remained normal until the sixth day after this inoculation, when the temperature again rose to 101° at 4 P. M. At 7 P. M. a third inoculation was given, using 50 mil. of streptococcus as the dose, and the next day the temperature was normal, the discharge from the punctured incisions stopped, and in another two days healing of all these areas occurred. After inoculation of 50 mil. of streptococcus on the fifth day after the last the patient was pronounced cured.

Four years after this occurrence I had occasion to see this patient at the home of one of her married daughters, whom I was called to see in consultation; she told me that whereas previous to this blood poisoning she had had attacks of facial erysipelas nearly every year for several years, the erysipelas had never returned since.

3. *The determination of correct intervals between inoculation.*—Incidentally, the last quoted case illus-

trates this point as well. After an effective dose, it is better to wait for the tendency to the recurrence of the temperature in order to determine the interval than it is to readminister vaccine by guessing at the intervals; it is more scientific, it will prove the value of vaccine by eliminating the conviction that a spontaneous cure has occurred, and will prevent the possibility of a negative phase by cumulative effect. Once the temperature has again shown a tendency to rise, the interval can be determined for future inoculations as one day before the expected return of rise in temperature. The fear is groundless that the return of temperature might bring back the severe condition where vaccine may not again prove efficacious; as when once vaccine is effective in a given condition, it will subsequently be even more efficacious in the same condition.

4. *The prevention of the growth of the causative organism, or the growth of new organisms beyond the reach of the antibodies.*—As the form of therapy with which we are concerned is an immunotherapy, our defense against the invading organism can be successful only so long as the invading organism can be reached through the circulation. But if the infection brings about a profuse serous accumulation such as occurs in peritonitis, or in pleuritic effusions, the antibodies, when carried into the effusions, are so diluted that but few organisms can be reached; on the other hand, these serous effusions form such fine culture media for the growth of the bacteria that, were we to permit it, this growth could far outstrip any defensive products the circulation might throw into this effusion to counteract it.

Having come to realize that our enemy is beyond our reach, we must adopt other methods in combination with our immunotherapy to counteract this possible invasion from his stronghold. That can be done by aspiration, by catharsis, by filling cavities with substances that will resist bacterial growth after the serous effusion has been removed. In the pleural cavity this is particularly effective by using olive oil to replace the aspirated serous discharge. The olive oil in the pleural cavity will not only fill the hollow when the expansion of the lung fails, but it will also act as a lubricant between the roughened parietal and visceral pleura. A host of other methods exist both to get rid of, when already present, and to prevent serous effusions, methods which the scope of this paper does not embrace.

Again, bearing in mind that an infection may be beyond the reach of antibodies, the failure of immunotherapy in cerebral infections may be accounted for. We know that the cerebral cavities are beyond the reach of the antibodies, and unless we use antitoxic substances injected directly into the cerebrospinal circulation, immunology must prove a failure here.

5. *The proper preparation of vaccines from growths of the causative organism.*—In dealing with autogenous vaccines, it must be borne in mind that slipshod methods may creep into a bacteriological laboratory as well as into any business institution. I know of instances where standardization is done by comparison of the opacity of the resultant suspension of bacteria in the normal saline with other opaque fluids, supposed to be equivalent to certain bacterial counts. Unless great care is exercised in the making of vaccines, autolysis of the bacteria may occur, making the vaccine innocuous. Again, it may not be amiss to mention that the improper treatment of the infected culture tube may play an important part in producing an inactive vaccine. For instance, if an infected culture tube is exposed to cold or allowed to lie around for any length of time, although we may get the microorganism to grow again when placed in an incubator at proper temperature, it may have become so attenuated that it will no longer stimulate antibody formation; or else its stimulation may become so feeble that it will have very little value as a vaccine.

In conclusion I would like to call attention to the fact that many elements enter into the use of the artifically induced immune response as a therapeutic agent besides those I have mentioned. And if the points I have brought out in this paper are not found as important as I wish to make them, at least let this writing serve as a warning against the disregard of vaccine in acute infections before a thorough analysis is made and the cause of failure discovered elsewhere than in the vaccine itself.

THE HISTORY OF CONDENSED MILK, WITH A NOTE ON ITS THERAPEUTICAL USES.

By PAUL BARTHOLOW, M.D.,

NEW YORK.

The history of condensed milk emerges bit by bit from beneath the records of kindred industries, as, for example, the refining of sugar and the evaporation of fluids and substances liable to decomposition. It deals with important subjects in physics and chemistry which have been stowed away from sight and have therefore been unduly neglected. It is almost essential in understanding the uses of condensed milk that we should know something of the principles upon which it is made, yet this knowledge has hitherto ended at the "curtain" or peroration of the lecturer or manufacturer when introducing condensed milk as a food for children and babies. The mere mechanics of the subject should preserve us from a view so superficial.

Some of the contributions to this science do not demand much notice. The dissertation of Braun, and the brief history of Hosford in the *Milch. Zeitung* several decades ago, come to nothing, or next to nothing, for they describe methods of manufacture that have long since gone to pieces. Mohan, indeed, has given us something more in a brief reference to the patents of Newton and of Green, but it is not clear whether he has read the original specifications or not. For, as to Green's patent, it cannot be stretched to cover any method related to the manufacture of condensed milk.

The invention of the process really originated with Howard, whose vacuum pan recalls some names illustrious in science and trade. It was invented, wrote Maumené in his "Fabrication du sucre," t. i., 3, in 1816. The account of the apparatus was given by Howard's friend, Thomas Thomson, in the *Annals of Philosophy*, 1816, Vol. 8, p. 209, which was translated and published in the *Annales de chimie et de physique*, 1816, p. 373. "In the ordinary way of boiling sugar, the temperature is so high that a considerable portion of the sugar is converted into treacle. Mr. Howard's vessels are globular, and of copper, and connected with an air pump, which is wrought during the whole time the boiling goes on. The consequence is that a vacuum is formed within the boilers. This enables the boiling to take place at a temperature so low that there is no risk of destroying any of the sugar. The vacuum is such as to support a column of mercury from one to four inches in height. There is a thermometer attached

to each boiler, and likewise a mercurial gage to give the degree of rarefaction." (From A Short Sketch of Mr. Howard's New Process of Refining Sugar). Manufacturers of sugar and of condensed milk have made full use of this invention. The vacuum pan described in Thomson's memoir is virtually the same as the globular and cylindrical apparatus in use to-day. According to Foster (Treatise on Evaporation) "the vacuum pan is quite as old, even older than the multiple apparatus . . . it has the same unpractical globular form, low and confined evaporation space, small heating surface."

These passages describe the vacuum pan used in refining sugar and in condensing milk; they show that the two industries are inseparably connected. Even the multiple system of Wellner-Jelinek by which large surfaces of milk or sugar are exposed to evaporation, is used by some manufacturers, in making evaporated milk, which in this context must not be confounded with condensed milk. It is certainly important that Howard's vacuum pan has given such an impulse to the manufacture of condensed milk.

What must be regarded as the most valuable feature of Howard's system is generally found in the manufacture to-day. In nearly all factories the vacuum pans are worked upon the general principle of Howard's. The air is kept, by the working of an air pump, at such a state of rarefaction that the milk boils at a temperature too low to cause browning, and the other changes incident to exposure to a temperature of 100° C. By carefully regulating the supply of heat to the pan, and of cold water to the condenser the progress of the operation being watched through a glass plate in the roof of the chamber, the condensation is carried on at a rapid but uniform rate until completed. The milk after sugar is added is raised to such a temperature that it may begin to boil immediately when brought into the rarefied atmosphere of the vacuum pan.

Richmond in his "Dairy Chemistry" refers to the multiple evaporation system, without, however, telling us where it is employed. A vacuum pan with a fairly large vapor space is used by the best manufacturers in America. The heat is carefully regulated, as well as the cold water to the condenser, and the milk is boiled at an even, rapid rate until concentration is sufficient, a point easily told by an experienced operator. The pans have a large heating surface, fitted with coils, as in the Wellner-Jelinek system. There is a high vapor space and low boiling level, unlike many pans in which the steam coils occupy most of the space, leaving little or no room for the charge. In a really good and modern pan the full charge is only 0.1 to 0.12 meters above the top row of tubes, which are of copper. These tubes are placed in 2, 3, or 4 rows, according to the size of the pan, and heated separately with steam. A high vapor space in the pan is indispensable to the manufacture of a good brand of condensed milk, since it allows the dispersion of gases from the mass of boiling milk. Such a system, however, is in my experience not often seen, the proof being the low standard of condensed in the constituents of the original milk. According to Tibbles, these variations in the composition of condensed milk are so great that it is essential that some standard should be fixed. Now, a medium quality of cow's milk would contain before condensation 3.3 per cent. of fat, and condensed to one-third its bulk 10 per cent. of fat. Such milk should also contain 8.5 per cent. of solids-not-fat before evaporation, and the condensed substance at least 25 per cent. of solids-not-fat. It has therefore been an established custom of the British Government to stipulate that it should contain not less than 10 per cent. of fat, and 25 per cent. of solids-not-fat. The Board of Agriculture made the following regulation under Section 4 of the Food and Drugs Act 1899.

"That any condensed milk (other than that labeled 'Skimmed Milk' in conformity with provisions of Section 2, Food and Drugs Act, 1899) in which the amount of milk-fat is less than 10 per cent., or the amount of solids-not-fat is less than 25 per cent. shall be deemed to be so deficient in some of the normal constituents of milk as to raise a presumption until the contrary is proved, that it is not genuine."

This English rule is a good one, and should be followed.

It is now more than fifty years since Gail Borden first manufactured condensed milk on a commercial scale. In 1856 he received a patent for a "process for concentrating sweet milk by evaporation in vacuo, having no sugar or other foreign matter mixed with it." Readers of advertisements naturally conclude that he invented condensed milk; at least that is the impression these advertisements make until corrected. But there is no doubt in the minds of those who have studied the history of condensed milk in detail that it was a Frenchman who first thought of it, and an Englishman, named Newton, who perfected it. The Frenchman was Appert, who in 1809 published his "L'art de conserver toutes les substances animales et végétales." This little book, which is now extremely rare, was dedicated to Gay-Lussac. At the time Gay-Lussac was a Member of the Board of Arts and Manufactures. His opinion of Appert's method is of particular interest. "The Board of Arts and Manufactures," he wrote, "has reported to me the examination it has made of your process for the preservation of fruits, vegetables, meat, soup, milk, etc., and from that report no doubt can be entertained of the success of such a process. As the preservation of animal and vegetable substances may be of the utmost utility in sea voyages, in hospitals and domestic economy, I deem your discovery worthy of an especial mark of the good will of the government."

Appert tells us how he condensed milk, "reducing it to two-thirds of its original volume." He sweetened it with sugar, though sugar, he says, is "hurtful to the patient." Evidently he disliked sugar. Indeed, his opinion on its use for preserving milk might have been written at the present day. I quote it at length. "A second inconvenience is this, that a large quantity (of sugar) is required to preserve a small quantity of milk; and hence the use of it is not only very costly, but even in many cases pernicious."

It is clear that the original idea in condensing milk was to preserve it, and its appropriate uses are equally distinct. Preserved or condensed milk was intended for armies, fleets, and hospitals, and not at all for children or babies. An English translation of Appert's work was published in London in 1811. Englishmen followed Appert in his process, and a patent for evaporating milk in a vacuum pan, it is stated vaguely by Mohan, was granted to Green in 1813. I have been unable to find this patent in the Specifications of British Patents. But there is a patent that was granted to Green in 1850 for the "preservation of substances liable to decomposition and destructive agencies." (Eng. Pat. 13,420.)

There is no doubt, however, that the process of

condensing milk in vacuo was fully developed in 1835 in the patent granted to Newton. (Eng. Pat. 6787, 11 March.) As the words of the specification tell the story of the original condensed milk, it is worth while to repeat them. (Specifications of British Patents 1830-1835.) "A method for preparing animal milk and bringing it into such a state as shall allow of its being preserved for any length of time with its nutritive properties and capable of being transported to any climate for domestic or medicinal use."

"Taking the milk in a fresh state, as drawn from the animal, having first strained it, if necessary, to get rid of any dirt or other improper matter which may have accidentally fallen into the pail or other vessel while milking, I introduce into the milk a small quantity of pulverized loaf sugar, say, from fiftieth to one hundredth part in weight of the whole quantity of the milk, which quantity may, however, be greater, dependent upon the desired sweetness of the preparation when completed. On the sugar becoming perfectly dissolved I subject the milk to a tolerably rapid evaporation, either by blowing through the milk warm or cold air by means of a suitable apparatus of any convenient form such, for instance, as those at present in use for evaporating syrups, or by means of external heat in connection with a vacuum above the surface. . . . Warmth will best be obtained from hot water or from steam, or heated air. . . . By evaporating the aqueous particles of the milk in this way, its nutritive or essential parts may be concentrated, and its substance reduced to the consistency of cream, honey, or soft paste, or even into dry cakes or powder, and may in the latter states be exposed to the air for a length of time without being impaired, the sugar tending to preserve it. By dissolving the milk so prepared in a proportionate quantity of warm or cold water the original milk is reproduced, with all its properties, original flavor and salutary qualities."

These early methods of making condensed milk proved most expensive undertakings. Though the quality of the product was good, even superior, the quantity was clearly not great enough for the needs of fleets, armies, and hospitals. It is therefore no small achievement of Gail Borden to have manufactured condensed milk on a scale meeting commercial conditions and requirements. I am inclined to think that the article he produced in 1857 was of better quality than the present brands. In 1857 a committee of the New York Academy of Medicine published a report on condensed milk after a visit to Gail Borden's laboratory. The details are not complete, but enough is said to make a not unpleasant picture. In the following words we get the impression of a primitive process, but one which is not tainted by modern arts. "The milk, immediately after leaving the cow, was strained into an ordinary milk can, then placed in a cold water bath until it was entirely deprived of its animal heat. It was then heated to a temperature of 175° Fahr. The milk is now passed through a second strainer, and without delay removed to a vacuum pan, where water is evaporated. This pan consists of a large metallic vessel supplied with a jacket for the reception of steam, by means of which heat is applied." It is not stated whether sugar was added. The uses of this condensed milk are appropriately noted. It "imparts a delicious flavor to coffee, and whenever used in the various departments of the culinary art has given entire satisfaction." At the end of the report the committee publishes letters from the stewards of steamship companies praising the milk as an article of food on long voyages.

The indications for the use of condensed milk are plain. It is both a food and medicine: a medicine for invalids, the sick in hospitals; a food for soldiers, sailors, and travelers. Its chief fault is the seductive sweetness that makes such an appeal to children. Again, the saturation of low-graded milk in sugar is a source of profit to manufacturers. At present the conditions of trade are such as to make the original uses of condensed milk more significant than ever. The food crises in Europe has reached such an acute stage as to necessitate the constant production of condensed milk for the armies and adult civil population.

THE PROBABLE FUTURE EVOLUTION OF INSURANCE MEDICINE.

By H. E. MACDONALD, M.D.,

Los Angeles, Cal.

Lecturer on Life Insurance Examination, College of Physicians and Surgeons.

Life insurance is now doing a wonderful work but its present field of operation is greatly restricted; whether necessarily so is subject to argument but that it should be enlarged, if possible, is not a matter for dispute, because even a casual observation discloses the fact that as the business is now conducted the life insurance agent is laboring under an almost impossible condition—those who are able to secure life insurance do not urgently need it while those who need it most cannot get it. Let us see if the present unsatisfactory condition is necessary and, if not, how it may be remedied.

The average duration of life does not change rapidly from generation to generation. It is true the potential longevity of man now is only a fraction of what it was in antediluvian times and actuaries tell us it is now being shortened in each generation. It doubtless will continue to fall so long as doctors rely on the augmentation of immunity to prevent disease, (see "Physiology and Pathology of Senescence," *So. Cal. Practitioner*, May, 1911), but by using the statistics compiled in recent generations it is possible to quite accurately estimate the average duration of life in this generation. Therefore it is safe to insure the inhabitants of a country basing the price charged upon mortality tables; it is also safe in the same way to insure all the inhabitants of a state, even of a healthful county. It is not safe, however, to insure those who voluntarily apply for insurance because it was found early in the history of insurance that those who are anxious about their health are prone to apply for insurance while those in good health do not seek it. This character of human nature is a thorn in the

side of the insurance business. With the discovery of this trait in men there appeared two new factors in the insurance scheme—the agent to solicit the healthy, and the medical examiner to keep out the diseased.

But the entrance of the doctor into the insurance business marked the beginning of the end of insurance as it is now conducted. The plan of life insurance based on mortality tables of average lives has no place for the medical examiners. Ignorance of physical condition is required for life insurance to be ideal, and just as knowledge of the health of applicants comes in, the pure insurance feature will go out of life insurance, for common honesty will demand that the cost of insurance will depend on the individual risk if this risk be known and, to carry the thought to its ultimate conclusion, if death could be accurately anticipated life insurance would be a crime.

This of course would not affect the legitimacy of accident insurance, and accident insurance, if we cling to mortality tables while using medical examiners, is certain to be *the* insurance of the future. If we exclude present infection in an applicant by scientific test and demonstrate, by examination, a normal nervous system, a perfect heart, soft arteries, good lungs, healthy kidneys, and a digestive system in good working order, then it is not life insurance he needs so much as accident insurance for almost any illness he may contract will be accidental.

I might say, in passing, that accident insurance of the future will cover infection, because contracting an infection is generally as accidental as a lick on the head. The present line drawn by accident companies between sickness and accidental injury is a purely imaginary line. For instance, they admit that ptomaine poisoning is an accident, but claim autointoxication is a disease. The fact is autointoxication, so-called, is often caused by putrefactive germs in the intestinal canal. It follows the only difference between this form of autointoxication and ptomaine poisoning, as recognized by accident companies, lies in this: in ptomaine poisoning the germs make the ptomaine outside the body while in autointoxication the ptomaine is made inside the body, a distinction too fine to be drawn. Accident insurance in the future will cover infections and a premium will be charged commensurate with the risk involved. This will eliminate the dissatisfaction now prevalent and it will demand a thorough examination by accident companies.

To get back to life insurance, the ideal insurance is state insurance where everybody, sick and well, is compelled to carry a certain amount of insurance, the premiums charged being the premiums of our life companies to-day. At the present time this is impractical. But is life insurance as conducted to-day a dishonest business? No, it is not dishonest but illogical. The managers and actuaries probably honestly believe they are running the business on the foundation of the average expectation of life as shown by mortality tables. But some men by actual measurement are as old at 30 as others at 60. (See "How Old is Ann?" *So. Cal. Practitioner*, September, 1916.) The fact is life insurance is run on the firm foundation of medical science and the ability of examiners to measure the expectation of individual lives. If this be true there is no logical reason why insurance should not be issued to sick and well alike. The mortality in typhoid fever, for instance, is just as uniform as is the mortality experienced by the various insurance companies.

We, the medical examiners, are willing to assume the responsibility of making prognosis in all cases and will promise to place the actual mortality as near (if not nearer) the expected as we do at the present time. Now we are asked simply "Is this a good risk?" Then we will be able to say how good or how bad.

If the insurance business continues to be conducted by private corporations there is bound to come a time when life insurance premiums will be made according to the risk involved. This means competition in prices. It also means examinations or appraisements and price-making before insurance is sold. It will also require thoroughly scientific diagnostic and prognostic methods. At first thought it may appear that this would be a very expensive method of conducting the insurance business but I believe it will be almost free from expense.

Suppose an insurance company decide to conduct their business in this way. They will hold their examination in prognosis after the graduation of a class in a medical college. Those who pass will be appointed examiners whose duty it will be to examine insurance prospects for a small fee or nothing. In doing this they will immediately have a practice, unremunerative it is true, but it will grow into a paying practice which will be along the line of preventive medicine, which will be the medicine of the future and which will be ushered in immediately by this plan of making life-insurance examinations.

That the procedure may threaten to undermine the whole structure of medical ethics will not stop it and there will probably be a way to avoid this catastrophe. Who knows that competition in prices in the insurance business may not ultimately be the life of the insurance business as it now is of every other business?

But whether they insure substandards or not the company that adopts the plan of examining prospects and suspects free of charge is going to get the lion's share of the insurance business. It will put new life in life insurance and will take the drudgery out of the present agency methods.

Baker-Detwiler Building.

Alcoholism a Symptom.—W. A. White states that a normal man does not become an inebriate. This goes counter to the accepted belief that an alcoholic has simply been overcome by a habit-forming drug. Take away his drink and he will never become normal. Inefficiency to face the world leads him to resort to liquor, and when he is deprived of the latter he still remains inefficient. Some men also have periodic psychoses which may be ushered in by a drinking spell and cease to want drink when the psychosis has ceased. Inefficiency is accompanied with a desire to escape the sense of reality, which may lead a man to shut himself up and drink to stupor. From the author's viewpoint alcohol in such cases is never a stimulant and differs from a mere habit-forming drug which call for use in ever increasing amounts.—*Interstate Medical Journal.*

Treatment of Human Rabies.—Geiger reports thirty-three cases of rabies in man occurring in a recent epidemic in California. Nine people had begun or finished the Pasteur treatment, but according to the canons of treatment in only three of the nine is failure to be charged. Short incubation period showed extreme virulence, and twelve patients had been bitten about the face. The average duration of illness was three days. In but six cases had the bites been cauterized. There were two cases of pseudo-rabies, one simulated and the other hysterical, which are not included. The dog accused remained healthy. No sedative was of any avail, and this is true of quinine. This is an old remedy recently revived.—*California State Journal of Medicine.*

CHEMOTHERAPY OF TUBERCULOSIS.

THE many failures in the field of serotherapy during the past quarter of a century, beginning with Koch's discouraging fiasco in 1890, and the large measure of success obtained with salvarsan and similar products in the treatment of syphilis, not to mention quinine in malaria and ipecac in amebic dysentery, have turned the attention of experimenters and clinicians to the possibilities of chemotherapy in the conquest of disease. As ever, tuberculosis is the touchstone in all those attempts, and this for many reasons: it is the most common of all mortal diseases, so that material for study and experiment is never lacking; its germ is known, so that experiments *in vitro* as well as by animal inoculation are easily carried out; its course, once it has reached the second stage, is so almost invariably progressive that its arrest under any method of treatment would seem fairly attributable to the measures thus carried out; and finally the fame to be accorded one who discovers a real cure of the disease is so great as to tempt many to put forth their best endeavors to obtain it.

One of the latest of these experimental studies has been made by Gensaburo Koga of Tokyo who makes a preliminary experimental and clinical report in the *Journal of Experimental Medicine* for August, 1916. He used a compound of copper and potassium ferrocyanide treated in a special way so as to prevent the formation of free hydrogen cyanide. In the animal experiments, in which over 150 guinea-pigs were used, the preparation exerted a decided action upon the tuberculous lesions. A single injection was without any appreciable effect, but after repeated injections a decided regressive change was observed in the lesions and the number of bacilli decreased until they were finally no longer to be found on microscopical examination. That the tissues were not absolutely sterile, however, was shown by the fact that injection of emulsion of the same into the peritoneal cavity of guinea-pigs was followed in some instances by the development of tuberculosis.

Trials of the copper cyanide in the treatment of human tuberculosis were made in a number of cases, reports of eleven of which are given in some detail. The author's conclusions, which seem to be justified by the reports, are "that the preparation greatly improves or apparently cures pulmonary and surgical tuberculosis in the first and second stages, and that it seems also to produce beneficial effects upon the disease in the third stage. The duration of those beneficial efforts is still to be established by more numerous trials and many years of observation." In the same journal is a report by Morisuke Otani of eighteen cases treated with Koga's preparation, in a number of which very favorable results were obtained, though in some absolute failure was noted.

We have thought it worth while to comment upon these experiments, in spite of the fact that Koga does not give directions for the preparation of the drug, apparently therefore intending to keep it secret, because they present a strong argument in support of the value of chemotherapy in tuberculosis and, by analogy, in other infectious diseases. The trustworthiness of the reports and the repute of the authors may be accepted on the authority of the journal which publishes the papers. It is not to be supposed, however, that there is only one preparation that is sufficiently parasitotropic and not too organotropic to be efficacious in the treatment of tuberculosis and other bacterial diseases; indeed we have considerable evidence to support Barton L. Wright's claim that succinimide of mercury has this property and that tuberculosis and many other infections may be controlled by intramuscular injections of this drug. Its efficacy has apparently been proved in various diseases by a number of observers and it possesses the great advantage of being an open remedy, always to be had, and available by any one of ordinary competence. Kago's and Otani's reports are of great value as affording additional testimony regarding the efficacy of chemotherapy in bacterial infections, and the experience of Wright and others would appear to justify further trials with succinimide of mercury along this line of therapeutic endeavor.

THE DEVELOPMENT OF PHYSICAL RESERVE FORCE.

WHATEVER other significance there may be in present-day military movements in the direction of preparedness, it indicates a physical renaissance that must redound to the good of the race generally and to its stability particularly. Physical improvement, as such, even if separated from a mental improvement of the race, is of great benefit. Physical development the result of healthy indulgences can go a long way to overcome the unhealthy tendencies, the sedentary life, and the vices of present-day civilization—to such an extent the forerunners of physical and mental decay. Perhaps the enormous increase in the mentally deficient is actually the result of these tendencies, and not merely relative, as is so often claimed. In any event, even the training of these defectives must be essentially a physical one. First, they must be taught the muscular power and the muscular coordination before they are prepared for much mental training. "A crooked mind in a crooked body" is as true as it ever was. The oft-repeated charge that a great mind and a great body do not go hand in hand is not true. The college athlete with a poor record in

his mental work is a poor student only because all his attention, all his time, and all his energies are directed to the athletic pursuits to the neglect of the mental. There should, of course, be maintained a proper balance here, as everywhere. In the building up of the body it is not the barbaric sport that is demanded, or the highly competitive, but rather the rational sport aimed at the development of definite muscle groups and the general increase of their resisting power or reserve force. The barbaric and the highly competitive sports are signs of physical decadence, in which the decadent, being themselves unable to get personal benefit from physical exercise, demand this from others to stimulate their failing powers.

The importance of increasing the muscular power and the muscular reserve is at once apparent when it is realized that the muscles are really the internal organs of respiration, wherein the interchange of blood necessities takes place. The increase of muscular power increases the extent of this respiratory membrane. The tendency toward physical training, as well as its specialized form, military training, does not aim so much at the increase of the actual physical power as at the increase of the reserve power. The former, no matter how small, is usually sufficient to mainttain ordinary bodily needs. But the ordinary muscular force is wholly inadequate to sustain any unusual demands of the body, whether from disease or otherwise, and against which the body must be prepared. The laity speak of the increase of reserve force as a "hardening" process. Under this conception it is believed that any hardship or discomfort increases the body reserve, and that the more suffering and hardship the better. The more comfort and ease under which one lives, the less reserve force there is developed—because not needed—and the "softer" they become. Hardening is exercise of the wholesome kind against resistance. It must, however, be done with an eye on the actual powers of the body, from the standpoint of endurance. The amount of fatigue must never rise beyond a point where the fatigue products can be easily absorbed and the body recuperate. Otherwise, whatever increase of power there is will be actual, and needed to drive a less easily running human engine. There may be increased muscular power, but it will be bound—"muscle bound" to the actual needs of the body.

To be rational, the hardening process, or the reserve building, must be periodic and ever increasing. The body must be immunized, so to say, against a certain amount of fatigue toxin before it attempts to incur more of it. The belief that the body can be placed indiscriminately in positions of discomfort and hardship which will of necessity be the means of improving it is fallacious. For a body that is already on the ragged edge this sort of immunization may be fatal. In actual immunization methods, contraindications especially include the ill, the weak, and the sensitive. The injection of bacterial products often produces a negative phase that is too much for them. In muscle building, this same negative phase must be reckoned with, otherwise there will be exhaustion and collapse.

The advantage of building up a reserve force is well illustrated in cardiac conditions. A break in compensation is really a lowering of the reserve force, no matter how large is the actual force generated to drive the blood against increased resistance. A reserve force of varying height is necessary to prepare the heart against any emergency demands made upon it. In the normal heart, the reserve force is always many times that of the actual force. And while this same condition is of prime importance in the muscles generally, and should be developed either by systematic physical training, by "hardening," or by military training, it should be encouraged only under proper guidance. Each individual must have prescribed for him the proper kind and the proper amount of physical exercise, else there will be a great many who will suffer from the general application of a good principle, that should have been applied specially.

THE TOO-READY WRITER AND THE HIGH COST OF PAPER.

THOSE who are in possession of the facts have for years been deploring the extravagance of the American people with their resources, and nowhere is this national failing more strikingly emphasized than in the paper industry. Whole forests are laid waste to feed a paper mill which, when it has exhausted one region, moves on to another, leaving behind it a scene of ruin. If all the old paper and rags were hoarded by the housekeepers for sale the result would be a decrease in the price of paper and a resultant double increase in the family finances, from both buying and selling. Already magazines are feeling the high cost of paper; some have increased their subscription rates, others are contemplating this step. Some English medical periodicals are economizing by issuing a limited quantity of their annual indices and supplying them only to subscribers who write and ask for them.

George Eliot speaks somewhere of the too-ready writer. He has a facile pen and delights to exercise it. Undeterred by the superficiality of his knowledge of a given subject he plunges boldly in, eking out his remarks by glittering generalities whenever he feels himself at a loss for real material. The more he writes on a subject, the more clearly he reveals the tenuity of his information to the experts in that particular branch, and with it all he manages to impress some with his versatility. We are all familiar with the physician who goes around laden with reprints which he forces upon acquaintances. He is the same gentleman who persists in discussing every paper presented in the medical meeting whether he has anything to say germane to the subject or not. On examining his productions for a year we find as a rule little original work and that little first published in a leading periodical and then reprinted with slight revision in many smaller ones. One interesting case is dragged in *ad libitum et ad nauseam* to illustrate points in many papers and his references are nearly always confined to himself.

In view of the destruction of the forests to feed the paper mills, in view of the possibility of war with its privations, and for the sake of a long suffer-

ing public, will not the medical writer who has nothing to say, say it? The English publication *Nature*, which has been forced to reduce its size, in its issue of March 23d, hits the nail on the head when it begs its contributors to "confine themselves to essentials, points of prime importance, in order that our record of scientific works and events may still be as extensive as possible, though it must necessarily be less detailed." There is food for thought in this request. American medical writers would do well to avoid historical summaries, rehashes of text-book material, and unnecessary detail in the report of cases even though we have no Royal Commission on Paper scrutinizing our use of that necessity.

Fainting Attacks in Children.

This complaint attacks both sexes, but girls somewhat oftener than boys. Occasionally the fainting spells date from quite early life, but usually they do not appear until about the fifth year or later and are commonest after the beginning of the school age. In general features the attacks are very similar in all cases. The child is observed to "go white"; he may fall down but does not lose consciousness entirely, although in some cases he is dazed, or even only semi-conscious. Occasionally retching or even vomiting occurs, but in no case is urine voided involuntarily. The attack lasts for a period varying from a few minutes up to half an hour or even longer, and passes off gradually. Sometimes it is followed by a headache. The commonest time for the attacks to occur appears to be in the morning, often before breakfast, or while the child is getting ready for school. Many of the children are nervous and dyspeptic, but in a considerable number the general health is quite good and the appearance of the child is flourishing. The preceding statements are taken from an article by R. Hutchison in the *British Journal of Children's Diseases* for June. Despite the large number of patients with histories of fainting spells, the author saw but one attack himself. In his summary he neglects to state that the attacks are frequently repeated through a sort of cycle. The distinction from petit mal is readily made. In the cases narrated there is no mention of family history. The author is wholly unable to account for these seizures, and can only accuse the sympathetic. With one possible exception the heart's action was normal. The attacks disappear under improved diet and roborant measures. The literature of this subpect is extremely limited, but this is true enough of syncope in general. Since fainting seizures often represent epileptic equivalents, a further study of these cases might repay the trouble.

Venereal Disease in the Austrian Army.

It always happens that in a great war venereal diseases flourish. As the present European war is the biggest war ever known, so it is to be expected that venereal diseases should be rampant. That such is the case is stated in a paper contributed to the *Military Surgeon*, July, 1916, by E. Kilbourne Tullidge, formerly Captain-Surgeon in the Austrian Army. He points out that the statistics of the French, German, and Austro-Hungarian armies show that the number of troops both in the home zone and on the front are acquiring venereal diseases with results that far out-distance the records of any previous wars. Of the three important venereal diseases commonly met with, syphilis is the most frequently manifest among the soldiers, about 33 per cent. of whom are married men. Emphasis is laid upon the fact that prophylaxis is the one feature that stands out in caring for syphilis, and that all things should be eliminated that increase the lure of extramatrimonial sexual intercourse, not only during a soldier's active service but also at home in the communities and large cities. The writer insists that the whole subject of venereal disease not only in war time but in times of peace should be regarded and managed strictly from a hygienic-medical standpoint without regard for esthetic considerations. The day of prudery in fighting this disease is past, and the matter must be considered entirely from the common-sense standpoint of public health and safety.

News of the Week.

Poliomyelitis Epidemic.—With a total of 5,519 cases and 1,251 deaths to August 9, the epidemic of poliomyelitis in New York City still causes considerable concern. In the State outside of New York City, 630 cases had been reported to August 5 with 57 deaths. The disease has also made inroads into the adjoining States, and on August 4, the State Health Board of Pennsylvania ordered a quarantine against children under sixteen years entering the State from New York and New Jersey. Many of the towns of New York State and of New Jersey and Connecticut had already adopted more or less stringent quarantine regulations against children from New York City, and efforts have been generally made to prevent the traveling of children from one place to another.

The laboratory workers invited by Health Commissioner Emerson to study the epidemic and discuss possible measures for its control, met at the College of Physicians and Surgeons on August 3 and 4. Dr. Simon Flexner of the Rockefeller Institute was elected to preside, and two committees were appointed. The first, which is to study laboratory methods, is made up of Dr. Ludwig Hektoen, Dr. Hans Zinsser, Dr. Richard M. Pearce, Dr. J. W. Jobling, Dr. G. W. McCoy, and Dr. Theobald Smith; and the second, which is to study methods of prevention, of Dr. Victor C. Vaughan, Dr. M. J. Rosenau, Dr. William M. Park, Dr. Francis W. Peabody, Dr. John Howland, Dr. Augustus Wadsworth, and Dr. Charles C. Bass. At the close of the meetings a report was made to the Health Commissioner, of which the following is a part:

"The weight of opinion favors the view that infantile paralysis is mainly spread through personal contact, and measures have been directed chiefly from this point of view. Cognizance, however, has been given to additional methods of transmission, among which is the bite of insects. For sanitary purposes it is proper to consider that this disease is transmissible directly from the sick to susceptible persons, or indirectly from the sick through carriers. . . . In seeking to abate the epidemic, stress must be especially laid upon two things as is now being done: (1) The early recognition and notification of the disease, and (2) the immediate isolation of patients and cases of suspicious illness. Furthermore, on account of incomplete knowledge concerning the disease, measures known to be effective in checking the spread of other infections should be

portion are possessed of an immunity against any ordinary dosage from these specific infections. And, further, the race is a debtor to our profession to the extent of absolute prophylactic measures in two of these diseases.

Because of many etiological factors that tend to show kinship in these affections, a possible relationship between their separate organisms, it would seem rational to attempt to bring about a partial immunity against infantile paralysis, by the use of an allied antitoxin. I suggest, therefore, the use of the antitetanic serum as a prophylactic measure; say about 500 c.c. every week for three weeks or more, to all children known to have been definitely exposed. It may be that we would render unpalatable the nerve cells for that combination which is the peculiar terror in this disease. If we fail—we have at least tried, and done no harm.

HARDEE JOHNSTON, M.D.

BIRMINGHAM, ALA.

OUR LONDON LETTER.

(From our Regular Correspondent.)

NEW CHELSEA HOSPITAL—COLLEGE OF SURGEONS' MUSEUM—NATIONAL COUNCIL—CALCUTTA HOSPITAL SCHOOL—OBITUARY.

LONDON, July 15, 1916.

THE Queen opened the new Chelsea Hospital for Women on Tuesday. It is a red-brick structure of Georgian design and located within a few minutes' walk of the old hospital, close to St. Luke's Church. On one side of the way the houses have been recently demolished and the new hospital will form an important part of one of the many improvements which have gradually transformed the locality beyond recognition during the last forty years. Her Majesty had, as usual, a hearty reception from large crowds of people as she drove by and was received at the hospital by the Bishop of London, the Marchioness of Londonderry, the Countess of Ilchester, the chairman, the honorary treasurer, the senior surgeon, and a guard of honor of Chelsea pensioners in their old-fashioned scarlet coats. A bouquet was presented by the ladies' committee and Her Majesty proceeded to the board room, where the rector, the mayor and mayoress, and various officials were presented. The ceremony of inauguration took place in the out-patient department, where a great gathering of friends were assembled. The address of welcome having been read, the Bishop of London offered prayer and the choir sang a hymn which was composed by Sir Arthur Sullivan for the foundation ceremony of the old hospital thirty-six years ago. The Queen then formally declared the new building open, afterward making a tour of inspection of the wards, one of which is named after her, "Queen Mary Ward." At the old building excellent work was done for many years, but in course of time its accommodation was too restricted. The new effort was made possible by the gift by Earl Cadogan of the site, valued at £22,000, the promise of £10,000 from the Lunz trustees, and the release of a mortgage of £4,000 by the chairman, Mr. Dyer Edwardes, a dinner which realized £8,000, and a matinée £2,000. A sum of £30,000 is still required to set the establishment on a firm footing. The building is constructed according to the latest scientific ideas. On the walls the distemper used in the Lariboisière of Paris has been employed, which is said to last for eight to ten years. This is the first time of using it in England. The building of a new nurses' home must now be undertaken.

Professor Keith announces in the report of the Museum of the Royal College of Surgeons, of which he is the conservator, that at present it is closed except for those engaged in research. Donations to the collection have been nearly as many as during peace. The working staff has been reduced to three men. Last year the college undertook at the request of the Director-General A. M. S. the collection and preservation of specimens illustrating military surgery as met with in the present war. Over 800 specimens judiciously selected have, accordingly, been added to the War Office collection, classified by Dr. Colin Mackenzie. Last month members of the U. S. Army and Navy medical services visited the museum and examined the collection and the means of preservation employed. Dr. Cabot of Harvard also visited the museum with twenty-five medical men about to serve under him in France. Prof. J. M. Thomson has presented the collection of his father, Allen Thomson, to the museum. Professor Parsons has presented a series of clavicles and Professor Symington preparations showing how far the arrangement of the convolutionary pattern of a brain can be reduced from a study of endocranial casts.

At the first annual meeting of the National Council for Combating Venereal Diseases on June 23, Sir T. Barlow reviewed the work of the provisional executive committee. The council had been fortunate in the support accorded to it in all directions and meeting no opposition worth mentioning. Dr. Frederick Taylor, chairman of the medical committee, remarked that although the subject had been obscured by the closing of some special wards, as soon as certain promised facilities were afforded by the provision of treatment centers, the whole profession would rise to the occasion. Lord Sydenham was elected president and said that he had urged the election rather of a medical man, but had been overruled by those who preferred a layman with what was called an "open mind." The commission was indebted to the medical members, particularly to Dr. Mott, for much original matter in the report, which appeared at an opportune moment when it was most important to remove every preventable cause of racial deterioration. Moreover, all experience warned us of the danger of an outbreak of venereal disease at the close of a war. Some of the recommendations of the commission must await legislative action, but he hoped would not be forgotten, especially the suppression of quack advertisements and the modification in some degree of the marriage law. The council would remind the government of the necessity for the provision of centers at which diagnosis and treatment would be facilitated, and he gratefully acknowledged the presentation by the Grocers' Company of a syphilis ward at the London Hospital, which was the more commendable inasmuch as it could make no sentimental appeal. The council should also arouse and maintain the interest of the people and act as a general center of enlightenment, a task requiring no little influence with hospital committees and municipal authorities. Sir Rickman Godlee, chairman of the military committee, gave an account of the propaganda among the troops; there had been 1000 delivered to some 800,000 men in the various commands. Sir M. Morris paid a tribute to Lord Sydenham's chairmanship and said the report was likely to have a

more practical result than the report of almost any other Royal Commission.

The Calcutta School of Tropical Medicine bids fair to be a success. It includes a laboratory and a hospital; the latter, it is hoped, will be ready within a year, and the new eye hospital of the Bengal Government is to be erected opposite. Sir Leonard Rogers, I.M.S., is the first director of the institution, which owes its existence to so great an extent to his labors. To commemorate his services a committee has been formed in Calcutta to provide and place a bust or portrait of him in the school.

Dr. William Anderton of Ormskirk died on June 12 at 69. He held several medical appointments in the town and was chairman of the local Beekeepers' Association and had been appointed to act as judge at the coming show at Manchester.

Dr. William Alexander of Bournemouth died very suddenly of angina pectoris just as he had closed a hard day's work. He was 53 years old; took M.B., C.M., Aberdeen in 1887. Owing to ill health he went to South Africa, but returned at the opening of the Boer War and settled at Bournemouth, where he practised for the last 16 years.

Progress of Medical Science.

Boston Medical and Surgical Journal.

July 27, 1916.

1. Hemoptysis as a Symptom. Frederick T. Lord.
2. Common Sense and Consumption. John B. Hawes, 2d.
3. Sprains and Sprain-fractures of the Wrist Joint. A. C. Burnham.
4. A Study of Peptic Ulcer from the Diagnostic Point of View. Roscoe H. Philbrick.
5. The First Case in which Abdominal Surgery was Suggested for the Relief of Epilepsy. Hale Powers and Frank H. Lahey.
6. Prolapsus Ani in Adults. T. Chittenden Hill.
7. Scientific Research in Chronic Medicine from the Physiological Point of View.

1. Hemoptysis as a Symptom.—Frederick T. Lord has reviewed 549 clinical cases of hemoptysis and 307 instances of hemoptysis with autopsy taken from the records of the Massachusetts General Hospital. He states that judging from these cases it may be taken as a clinical rule, subject only to rare exceptions, that hemoptysis out of a clear sky, or when cough and scanty expectoration alone cloud, it is due to pulmonary tuberculosis. The rule seems to hold as well in those cases in which the hemoptysis occurs during a mild acute respiratory infection after exertion, moderate injury, or without any apparent cause. Exertion of itself cannot be regarded as an adequate cause of hemoptysis, but it may lead to bleeding earlier than would otherwise occur in a patient with tuberculosis owing to the added strain on the walls of blood vessels already weakened by disease. Initial hemoptysis, even though the only symptom, without subsequent manifestations of pulmonary disease and the maintenance of full health until life is terminated by some other cause, is to be regarded as of probably tuberculous origin. Of the various causes of hemoptysis in the probable order of their frequency pulmonary tuberculosis undoubtedly occupies the first place. It occurs in about 60 per cent. of all cases at some time in their course. It is represented among the 307 autopsy cases above referred to by only 27 cases, owing to the usual exclusion of patients in the active stage of the disease from the wards of the hospital. Chronic passive congestion probably occupies second place, but heads the list of the autopsy series with 105 cases. Then follow lobar (not broncho-) pneumonia, with 100 cases, pulmonary infarction with 48 cases, nontuberculous pulmonary suppuration with 14 cases, aortic aneurysm with 7 cases, new growths of the lung with 5 cases, and ulceration of the trachea and bronchi due to syphilis in one case. These records are of further interest in a negative sense because of their failure to confirm the still too prevalent belief that vicarious menstruation is an adequate cause of hemoptysis, no example of which was found in the autopsy series. Hemoptysis in the course of disturbances of the nervous system, in patients with the so-called "arthritis diathesis," and in those with high blood pressure, is likely to find its true explanation in one of the above mentioned groups. With reference to the influence of hemoptysis on the course and termination of the tuberculous cases the writer finds that for the most part the bleeding is intercurrent and without any appreciable influence upon the course of the underlying disease, but in certain cases the hemoptysis is a direct cause of the fatal termination; this was the case in five instances in this series. The danger of the retention of infected blood and consequent spread of the tuberculous process is constantly to be borne in mind in the treatment of hemoptysis due to tuberculosis, and it seems highly undesirable to use morphia as a routine as is so generally the custom in these cases.

2. Common Sense and Consumption.—John B. Hawes, 2nd, thinks that pulmonary tuberculosis is often wrongly diagnosed, and as a result many nontuberculous patients are sent to sanatoria and health resorts, where they run a grave risk of "catching" tuberculosis. He insists that the physician must always remember that he is dealing with a human being, and not merely a set of lungs normal or abnormal. While the diagnosis may justly be made on signs in the lungs alone, or on constitutional signs alone, in the vast majority of cases there is a combination of both. It is usually the careful study of the patient's history, his habits, surrounding occupation, and the constitutional signs and symptoms that he presents which is of paramount importance and which is most often neglected. In doubtful cases, it is possible and often wise to institute proper treatment without definitely stamping the patient as tuberculous. Above all things it should be remembered that from the patient's point of view, it is better to be "safe and sorry," better to undergo a few weeks or months of treatment and to gain physically by so doing, than to linger along in false security until the chances of cure are gone.

5. The First Case in which Abdominal Surgery was Suggested for the Relief of Epilepsy.—Hale Powers and Frank H. Lahey report a typical case of epilepsy operated on on September 17, 1914, a colectomy having been performed by Dr. Lahey. They believe that this operation undoubtedly assisted in the cure of this patient, though perhaps the patient would have been relieved had he been willing to submit to the régime upon which he was finally placed and which has produced equally good results in other cases. The reason for the resort to surgery and to the medical treatment outlined is based on the belief that in so-called idiopathic epilepsy the essential lesion is not in the nervous system but is dependent on gastric and intestinal stasis. The medical treatment consists in a diet excluding fried food, fresh white bread, pastry, beans, milk, except in moderate quantities only with meals, and uncooked fruit, except oranges, figs and dates. The diet list bears directions to the patient to chew thoroughly, eat slowly, never hurry after eating, and never to eat too much. The medication consists in bromides, thymol, and sodium bicarbonate when there is flatulency or abdominal pain. The author urges conservatism in the employment of colectomy in epilepsy and believes it should be reserved for cases in which rational non-operative treatment, with painstaking attention to de-

tail, directed toward the relief of the intestinal condition, has failed, and for cases in which, because of mental enfeeblement or for other reasons, the cooperation of the patient in the treatment cannot be secured.

6. **Prolapsus Ani in Adults.**—T. Chittenden Hill describes an operation for this condition which he has used with entire satisfaction for twelve years. The procedure is a modification of that of Mr. Goodsall of London. Local anesthesia is produced by infiltrating the structures with novocaine all around the anus to a level well above the internal sphincter, caution being exercised not to infiltrate within the muscular wall of the rectum, as this renders it difficult to estimate how much should be removed at the operation. The prolapsed fold of the right side is slightly elevated with a couple of hemostats and an incision made with scissors at the muco-cutaneous juncture about a quarter of an inch deep. While making moderate traction in a downward direction, the three curved needles, which have been previously threaded on a linen ligature a yard long, are passed in at the line of incision and brought out at the upper part of the prolapse in the following manner: The middle needle is first passed in the center, and the other two needles are inserted on either side of the middle one, thus dividing the fold into four equal portions. The four loops are now identified, the needles cut off, and each loop in turn tied very tightly. In this way the entire fold is completely strangulated, and as the ligatures are not interlocked, there is no occlusion of the anal canal. The operation is completed by excising a goodly portion of the mucous membrane below the ligatures, care being taken to leave enough so that they will not slip off. When the prolapse is bilateral the same procedure is carried out on the other side. The advantages of this operation are that it can be painlessly performed under local anesthesia, that it is short, that there is absence of hemorrhage, that the end results are always satisfactory, and that this method of applying the ligatures brings about a more normal repair than any other operation.

2. Anaphylactic Food Reactions in Skin Diseases.—Albert Strickler has studied 46 cases with eczema, a great majority of them being kept under observation for some weeks. Their plan had been, whenever possible, to withhold local treatment entirely to see what benefit, if any, diet exerted on the course of the eruption, as to both subjective and objective phenomena. From a study of the table presented it is shown that 50 per cent. of the patients were in a greater or lesser degree benefited by the changed diet, as shown by the anaphylactic food tests. In 26 per cent. the food tests were entirely negative, and in the remainder the correction of the diet, as shown by the food tests, did not have any bearing on the disease. In addition to the 46 cases of eczema, 10 patients with urticaria, 13 suffering with acne vulgaris, and 3 with acne rosacea, were studied. From these observations the conclusion is warranted that anaphylactic food tests are of value in the etiological diagnosis and in the treatment of various diseases of the skin. These reactions find their greatest value in eczema, where the development of a strong positive reaction holds out great hope for an improvement or cure in the skin condition, and in some instances an amelioration of the associated gastrointestinal disorder by exclusion of the incriminated articles of food. In chronic urticaria, acne vulgaris, and psoriasis the results of these tests are disappointing, inasmuch as the information secured from the cutaneous tests has not as a rule led to therapeutic success. A very weak reaction obtained by the endermic injections is not of convincing value, although it is advisable to correct the diet according to the findings. In chronic eczema the anaphylactic food tests offer hopes for the patient so far as the possibility of rapid improvement or cure is concerned and also with regard to conferring immunity against future attacks by the employment of prophylactic measures. It will no longer be necessary to starve the patient with eczema.

5. **Urinary Toxemia.**—Willard H. Kinney suggests that before making a diagnosis or prognosis in a case of suspected urinary toxemia the following questions be considered: 1. What pathological condition underlies the clinical picture? 2. Is the condition restricted to the kidneys, or is any other system involved? 3. What is the functional capacity of the kidney; is it permanent or temporary and subject to change? 4. Is the condition amenable to treatment? Clinical or functional studies alone are inadequate from the standpoint of prognosis. A perfectly normal urine may be excreted by a congenitally deficient kidney. Postoperative renal infection is more frequent than was formerly believed. Miller and Cabot have found the phthalein output usually diminished, especially after laparotomy and operations for cancer. Generally speaking, the diminution is proportionate to the amount of ether used and the length of the operation. Shock decreases the elimination of phthalein, while postoperative albuminuria is not in proportion to the phthalein reduction. In summarizing the treatment of urinary toxemia the author states that success depends upon one factor—elimination. He recommends calomel and high colonic irrigations. Hypodermoclysis and intravenous saline transfusion are indicated in certain cases. Diaphoresis is best accomplished by the dry hot pack, preceded by some cold acidulated drink and the application of an ice cap to the head. For the dry, furred tongue nitroglycerine, 1/100 of a grain every three hours, seems to be the best drug. Sparteine has taken the place of digitalis both as a diuretic and a heart stimulant. When hiccoughing occurs the administration of sodium bicarbonate or Hoffman's anodyne seems to be of use. In some instances there is a condition of apathy, with slight muttering delirium, and when these symptoms manifest themselves it is well to get the patient out of bed and into a wheeled chair. When drainage has been instituted careful watching for obstruction is imperative. It sometimes becomes necessary to perform bilateral decapsulation of the kidneys in order to restore renal function. In concluding the writer emphasized the following points: Prophylactic care before operation, careful clinical study corroborated by functional tests of the renal output, comparative studies of toxic retention in the blood as well as in the urine, careful selection of the anesthetic and speed in operating, close attention to maintenance of drainage when indicated, and to the renal output after operation.

8. Six Months' Work in Anesthesia.—Alma Vedin makes this report from the Second Surgical Division of the New York Hospital. The cases comprise general and gynecological surgery, as well as a small percentage of tonsils and adenoids. The routine method employed has been ether by the drop method, preceded by nitrous oxide in adults and ethyl chloride for young children. In head and neck cases, endotracheal or pharyngeal insufflation has been used, and in minor cases nitrous oxide and oxygen, or ethyl chloride. Chloroform has seldom been employed. In 656 cases in which careful records have been kept there has been no conscious vomiting in 334, or 50.91 per cent.; 210, or 32.01 per cent., had slight vomiting, whereas 112, or 17.07 per cent., had prolonged vomiting. Seventy-seven suffered from headache and 269 from varying degrees of thirst. Forty-five complained of cough; 13 of these were coughing before operation. It is generally thought that without a preliminary hypodermic of morphine and atropine the patient will suffer much with mucus, but this was found not to be the case. The postoperative pneumonias have been studied by Dr. Frederick Bancroft, who says that ether is the safest anesthetic, and its administration by the open drop method the safest and most practical method for the general hospital clinic. During the year 1915 there have been 15 cases of pneumonia among 1413 operations, or 1.06 per cent. Of these 46.6 per cent. proved fatal. One of the greatest factors in the etiology of postoperative pneumonias is the operative nightgown. The endotracheal method was used in 115 cases, and is considered as being especially indicated for operations in which it is inconvenient for the surgeon and the anesthetist to occupy the same field, as in thoracic surgery, brain surgery, and operations about the neck. It is particularly useful in thyroidectomies. Pharyngeal insufflation, while it may be satisfactory in the majority of cases, is not always absolutely smooth, as the catheters may become clogged with mucus and blood if the operation is in the mouth.

9. Bursitis Subacromialis. Treatment of the Acute Form.—Heinrich F. Wolf expresses the opinion that there exists an acute form of bursitis subacromialis, and that it is produced by various etiological factors analogous to those of acute articular rheumatism. A treatment which seldom fails consists of wet dressings kept on day and night, changed every twelve hours, high doses of aspirin, 50 to 60 grains daily, and very gentle massage.

1. The Care of Children's Teeth: The Most Neglected Feature of Pediatric Medicine.—Thomas C. McCleave. (See MEDICAL RECORD, June 17, page 1116.)

2. The Prognosis in Infantile Paralysis.—Walter G. Stern states that the death rate of epidemic infantile paralysis is as high as that of any of the most serious diseases of childhood. While a few perfect complete cures are authentically reported, the vast majority of patients make only a partial recovery of muscle power, with a more or less imperfect functional result. Spontaneous cure unassisted by treatment is at its maximum in from three to six months. Careful treatment—physiologic rest, graded massage, stimulating electric applications, resistance exercises, muscle training, etc.—improves greatly the chances for partial recovery and lengthens indefinitely the period in which such recovery can take place. Misuse, overwork, overstimulation, overexertion, contractures, and deformities are particularly harmful and detract from the power of recovery and often destroy what little muscle power has been gained. The prognosis for recovery in a given case depends on many factors, most of which represent unknowns, and only one being under the direct control of the physician. These are: 1. The amount of actual permanent destruction of the ganglion cells of the anterior horns, or of the brain. 2. The amount of nerve cell congestion and edema, and neuritis. 3. The regenerative and reconstructive powers of the nervous system. 4. The amount of muscle degeneration and overstretching (loss of tone). 5. The presence of bone and joint deformities. 6. The curative effect of proper treatment. The prognosis should always be guarded, conservative, and truthful, lest the parents, expecting too much, should in their disappointment throw away all rightful gain in strength, power, and function, while seeking the chimera of a perfect cure. With proper treatment, followed by braces, orthopedic operations, and the like, almost every patient with infantile paralysis should, so to speak, "be put on his feet" and acquire independent and useful function of the afflicted member.

3. The Necessity of Revising the Nomenclature of the Anatomy of the Brain.—William Fuller makes a plea for simplicity in the study of anatomy as in other branches of science. The use of generalizations and the elimination of numerous proper names would be a great help to the student. Structure and its supposed function should be considered together in giving a name to any part of the body, so that one reading the history of medicine might be able to compare the progress of one age with that of another. When found necessary names could be changed to conform with the understanding without much confusion by writing the old names in parenthesis. The change could gradually be made in this way with but slight embarrassment. The essayist cites two of the many absurdities of the present nomenclature. The cingulum (girdle) properly named should be called the superior internal logitudinal commissure, one of the four great longitudinal commissures associating the memories with the frontal lobe of the brain. This large tract arises in front from the olfactory and marginal convolutions, passes backward over the corpus callosum, then downward and forward, and terminates in the hippocampal lobe. A different name is applied to each of the three different parts of its course. As nearly all parts of the brain encircle the bundles of the internal capsule in the same manner, why select this particular girdle as the cingulum, when they could all be represented together in a single generalization? Again, there are the "forceps major" and "forceps minor"; the writer has dissected many brains and has failed to find them. Multiplicity of names could be avoided and simplicity attained by the adoption of a systematic generalization of the parts of the central nervous system in connection with that of the whole body. When the attempt is made to associate the knowledge acquired of the anatomy and functions of the nervous system with psychology or psychiatry we are in the presence of technical words and phrases of uncertain significance, and the situation might be

greatly cleared up if the science of mind can be reduced to a few basic principles easily understood, and from which all the phenomena relating to mind are evolved as the result of reflex action.

8. **A Bacteriologic Study of the Causes of Some Stillbirths: Preliminary Report.**—Joseph B. De Lee reports a case of a child of a healthy mother born with a temperature of 101° Fahr., which within a few hours rose to 103°. The child died of streptococcus septicemia, the mother showing no signs of infection. Later a physician's wife came under his observation who, after a mild pharyngitis, developed albuminuria and eclampsia. Artificial delivery was performed. Out of the child's nostrils pure pus exudated in which the pneumococcus was found. He reports additional cases that indicate that the child can become ill independently of its mother, and may even die, the mother being only indirectly affected, or not diseased at all. The writer thinks that this discovery opens up an immense field for study and that we may find that the cause of many cases of so-called "habitual abortion" and repeated premature labor after viability and before term, and that we may come on new problems of immunity, focal infections, nephritis during pregnancy, eclampsia, puerperal sepsis, blood-borne transmissions, and new aspects of the transmutations of bacteria.

10. **Discission of Crystalline Lens.**—Edward Jackson calls attention to the great variations that occur in the behavior of the eye following this operation, which he illustrates by extracts from a series of case histories. He concludes that for monolateral cataract up to middle life, discission is to be considered as a proper procedure; and in many cases the patient will prefer it to extraction. The first discission should make only a short opening in the capsule; but may well penetrate to the center of the nucleus, so that disintegration of the nucleus may begin as soon as possible. The amount of swelling from a given interference will be proportioned to the size of the opening in the capsule, and the absence of previous change in the lens substance. Severe reactions and surgical shock are provoked by the presence of large masses of lens substance in the anterior chamber. Possible hemorrhage, from making puncture through the vascular limbus, causes no danger to offset the greater safety from infection secured by this point of entrance.

2. **An Investigation into Some of the Effects of the State of Nutrition of the Mother During Pregnancy and Labor on the Condition of the Child at Birth and for the First Few Days of Life.**—G. F. Darwall Smith has investigated 6,162 cases obtained from the lying-in hospitals of London and Dublin. He concludes that his statistics do not absolutely prove anything, but they suggest that a state of bad nutrition of the mother at the time of labor due to insufficient food greatly increases the percentage of dead births and of premature births; it slightly decreases the average weight of the full time baby at birth; definitely increases the post natal infantile mortality; has little if any effect during the first eight or ten days of the progress of babies who live during that time, and possibly increases the death rate of babies during the first three or four days of life. A state of good nutrition of the mother at the time of labor, on the other hand, considerably increases the average weight of the full-time baby at birth and increases the percentage of mothers who are able to suckle during the first eight or ten days of the puerperium quite apart from any effect from the use of ample diet during this time. The figures also suggest that on the whole a state of average nutrition of the mother is the most favorable condition.

5. **An Experience of Galyl at Royal Naval Hospital, Chatham.**—Sheldon F. Dudley relates his experience with galyl, which he has substituted for neosalvarsan in the treatment of syphilis, having given about 1,500 injections. Taking the results as a whole, he finds that neosalvarsan seems to have slightly more power in producing a negative Wassermann than galyl. Clinically galyl seems to be almost as valuable as neosalvarsan, ordinary chancres and ulcerative lesions generally clearing up within ten days, but it must be confessed a few cases a month or so after injection still have the remains of a rash, and more rarely an unhealed sore, an event which in the writer's experience was exceptional with neosalvarsan. Still it can exhibit the same dramatic cures as the older drug. This fact points to arsenic as the important element in these drugs. The dose 0.4 gm. galyl contains just one-half as much arsenic as 0.9 gm. of neosalvarsan, which probably accounts for the slightly less therapeutic effect and lesser toxicity of galyl. It would seem that though excellent results have been obtained with neosalvarsan and mercury with a month's interval between the intravenous injections, this interval is unnecessarily long in the case of galyl. As the dose recommended has only half the arsenic content of neosalvarsan, the interval could be halved without any more likelihood of the occurrence of cumulative arsenical poisoning, and if this were done galyl would probably be as good an agent for the cure of syphilis as neosalvarsan.

7. **The Use of Tuberculin in General Practice.**—J. Linton Bogle reviews the general principles of tuberculin administration and calls attention to certain errors that are to be avoided. It is necessary to remember in passing from one dilution to another the strength is ten times greater, so that in changing from a smaller injection of greater strength the increases should be small. Again, dilutions newly made are stronger than old dilutions, and the extractive toxin tuberculin dilutions are less stable than those made from the ground bacillary bodies, such as T. R. It is desirable to make fresh dilutions every two or three weeks in the former case, and every four or six weeks in the latter. A nervous patient, tending to high temperatures or hemorrhage, requires smaller doses and of a slowly acting preparation, such as B. E., and hence the course will be lengthened. Although experts, with their knowledge and wide experience, may be able to use tuberculin in most cases of tuberculosis with benefit and without injury, there are cases in which the general practitioner would do well to avoid the use of this remedy. In mixed infections, catarrhal or bronchial;

in tuberculosis complicated by disease of the heart or kidneys; in rapidly advancing or extensive disease; in cases of high fever and quick pulse; in anemia associated with little power of resistance; in those in whom there is a strong hemorrhagic tendency, and in cases of infantile tuberculosis, tuberculin as a rule does no good. It is only in conjunction with rational general treatment that the striking results of this special treatment are manifest.

1. The Care of the Pregnant Woman.—Archibald Donald expresses the opinion that the supervision of all pregnant women would mean a great deal of unnecessary trouble, as in the majority of cases in which danger threatens during pregnancy the patient will voluntarily apply for help. His experience leads him to believe that even if supervision were greatly increased the results in the saving of infant life would be comparatively small. There are several much more important causes of fetal death than the diseases of pregnancy, and these would not be dealt with in a scheme of supervision during pregnancy. Under these the writer mentions particularly abortion and stillbirths caused during delivery. Furthermore, it must always be borne in mind that sterility, either absolute or relative, has a most important effect on the birth rate. If any improvement is to take place as regards stillbirths, it ought to be on the lines of the further development of those institutions which already exist. While the writer believes that the cooperation of the medical officers of health and the health authorities generally with the medical profession is most important, much more good would be done at much less cost if the cities were to subsidize maternity hospitals instead of creating a new system. If found advisable, smaller centers might be established under the hospital control in various parts of the town. The greatest stress should be laid on education. The pregnant woman should be taught how to take care of herself and warned of certain dangers that may arise. Midwives and medical students should receive a more thorough training. More facilities should be given for the medical practitioner to have postgraduate instruction. The study of the pathological problems connected with abortion and stillbirth should be stimulated by the provision of well-equipped clinical laboratories in connection with maternity hospitals. The solution of the matter is not in statistics and notification, but in education and research.

2. Tuberculins and Vaccines.—E. Hayling Coleman, writing from the general practitioner's point of view, says that in making a decision whether or not to use a vaccine, cases may roughly be divided into four groups: 1. Those in which a vaccine is usually successful and much more likely to succeed than other remedies. 2. Those in which ordinary remedies have so far failed and we know that a vaccine may cure, though not so frequently as in the first group. 3. Cases of serious disease, in which the use of a vaccine can do no harm, and may decidedly increase the patient's chance of recovery. 4. Cases in which, though vaccines often fail, yet other remedies do so almost invariably. Among the conditions belonging to the first group are recurring boils and carbuncles, chronic nasal and post-nasal catarrh when due to the pneumococcus, chronic tracheitis of old people, cystitis due to infection of the bladder by *B. coli* and chronic gleet; in all of these autogenous vaccines rarely fail. Under group 4 the writer discusses rheumatoid arthritis, and says that the most promising cases are those due to septic absorption from the pus about the teeth in pyorrhea. The vaccine should be prepared from this pus. His experience with this class of cases has not been very hopeful, and he feels inclined to believe that the difficulty is due to the dense tissues and poor vascular supply of the parts which are affected in this disease. In chronic suppuration of the middle ear he has also found the vaccines to fail. In discussing the use of tuberculins the essayist brings up the matter of mixed infections and says that most failures of tuberculin are due to this not being recognized. He has had some of his best results by combining Dr. Curle's nascent iodine treatment with B. E. He believes the iodine acts on the adventitious infection, and the B. E. then has a fair chance with its own bacillus. He has also seen good results from the use of a vaccine made from the adventitious organism along with tuberculin. Another point which is emphasized is that in treating a patient with tuberculin the sputum becomes less infective, the tubercle bacilli often completely vanishing, even though from the symptoms and physical signs it is evident that the disease still has a strong hold. This is of great value in preventing the spread of infection. Some fear giving tuberculin in cases with hemoptosis, but the writer has never known harm to follow provided the tuberculin is properly employed.

5. Acute General Hemorrhagic Peritonitis.—Arthur J. Nyulasy reports three cases of this condition which have come under his observation, two of them resulting from criminal abortion and coming to autopsy. One of these presented a striking lividity of the skin, involving the whole body. The third case, which is described in detail, is remarkable because of the absence of serious symptoms. This is accounted for partly by a preliminary diarrhea, and partly by the large quantity of blood which escaped from the engorged peritoneal vessels. The conditions found at the operation suggest that acute infective inflammation of the peritoneum is not *per se* nearly so serious as appears to be commonly supposed, and that, providing the focal factor and any free toxic fluid be removed from the abdomen, and that there is no paralytic ileus, the patient may recover with comparative ease from a most extensive acute infection of the peritoneum.

Acute Mammary Carcinoma. — Learmonth gives the large number of synonyms in use for this affection. In 1911 Schumann collected notes of forty-five cases from literature. Of 579 cases of cancer of the breast in the Johns Hopkins material, eight were of this nature. Rodman personally has seen seven cases. Leitch encountered two cases in five years' pathological work in London, and also saw four cases in Glasgow and one in Dundee. But one five-year recovery is on record (Bloodgood's case). As is well known the affection simulates a fulminating mastitis, and early in its course differential diagnosis is impossible. The disease occurs especially during pregnancy and lactation. The exact number of cases of these types is not stated. It is possible that certain cases of cancer of the nursing breast belong here (two are mentioned by the Mayos). Leitch found in his cases that medullary cancer predominated. Owing to the frequency of erroneous diagnosis, the outlook for this type of cancer is highly pessimistic.—*The Canadian Medical Association Journal.*

Insurance Medicine.

Typhoid Vaccination for Policyholders.—The following is from a letter to the policyholders of the Southland Life Insurance Company of Dallas, Tex., by Dr. W. A. Boyce, associate medical director: "It is not our purpose to prescribe what rules should be followed regarding the prevention of typhoid. This is fully covered by the bulletins of the various health departments and the federal authorities. We do wish to call attention to the fact, however, that, supplementing the precautions as advised by the health authorities, it is most desirable that everyone be immunized against this disease by being vaccinated with antityphoid vaccine. That antityphoid vaccination is successful in almost absolutely preventing the disease and, in any event, lessening the severity of it, has been clearly demonstrated in the tests of the vaccination made at San Antonio in 1911 upon enlisted men in the U. S. Army as well as in the French Army and the British Army in India, and other places. As antityphoid vaccination has met with such success, the Southland Life Insurance Co. offers to all of its policyholders the advantage of this vaccination free of charge. Our physicians will be on duty for this purpose from 2 to 4 p. m. each business day except Saturdays. We will endeavor to handle all cases as expeditiously as possible, but to avoid unnecessary delay it is requested that those desiring to take advantage of this offer notify this company in advance, so that proper arrangements may be made. Assignments will be made in the order of application for treatment."

The Obligation of the Medical Examiner.—Dr. Henry Wireman Cook, in a paper with this title, read before the Section on Life Insurance, State Medical Association of Texas, said that the obligations of the work of life insurance examining might be divided for study under three general heads: (1) Moral obligation; (2) Business obligation; (3) Professional obligation. With regard to moral obligation the confidence implied in an appointment as examiner should not only guarantee the best professional service, but should bring loyalty, interest, and cooperation. The medical report should be absolutely unbiased by the importunities of the agent, the demands or threats of the applicant, or the appeal of the prospective widow or orphans.

An for the business obligation, in insurance underwriting, promptness is a most vital factor. A delay by the examiner of twenty-four hours in completing an examination may cost the agent several hundreds of dollars, which he has earned by weeks of hard work. All the ordinary business demands must be observed in insurance work: Courtesy, tact, promptness, rapidity, and accuracy on the part of the examiner are of equal importance to scientific requirements.

The scientific obligation is the part of the service that is most clearly recognized and understood, and yet it is frequently covered in a careless and indifferent manner. The work of a general practitioner, owing to the insistent demands upon his time, is apt to become superficial and hurried. In insurance work the one examination is final, and on its representation must be risked a liability for thousands of dollars. Careless methods which may be corrected in practice are disastrous in insurance work. The examination must be approached in an orderly manner, and each detail given systematic attention.

The personal history of the applicant is a very important factor. The difference in attitude of a patient and an applicant cannot be too strongly emphasized. The patient is fluent in the description of his symptoms, his indiscretions in habits, his previous illnesses. The admission of such impairments must often be drawn from an unwilling applicant by patient and skillful questioning. This, of course, is particularly true of an impaired applicant who is attempting to obtain standard insurance, and in such a case a correct history is vital. A true history of alcoholic excess or venereal disease is naturally extremely difficult to obtain, as few men hesitate to misstate these answers. In the physical examination proper, a physician has an opportunity to use to the utmost his skill and knowledge.

The applicant will not submit to such an examination as we can give a patient. The work must be done quickly, and a judgment based on a single interview. It is therefore particularly important that the examination should be made systematically, carefully and thoroughly. There may be no second opportunity to correct mistakes and omissions. The general condition of the applicant must be carefully noted. An impaired risk frequently "looks" impaired without any definite lesion being discoverable. General tendencies should be borne in mind: for example look especially for signs of tuberculosis in young light weights, where there is history of indigestion, recent change of climate; look for thickened arteries, high blood pressure, casts and albumin in men over 45, in the obese, in high livers, in applicants with short family history and with several cases of apoplexy, heart disease, or Bright's disease in the immediate family.

No part of the physical examination furnishes less satisfactory data in proportion to its importance than the urinalysis. The average physician fails in this work because of the neglect of a few simple requirements. There must be a strong bright light, a dark background, clean test tubes, properly prepared reagents, and a little care and time. The Ulrich modification of the heat and acid test is recommended for this purpose.—*Texas State Journal of Medicine.*

Dilatation of Heart Following a Cold Bath.—Where an insured holding an accident policy indemnifying him against bodily injuries which, independently of all other causes, are effected solely and exclusively by external, violent, and accidental means, suffers an injury due to the dilatation of the heart, following the voluntary taking of a cold-water bath, it is held in New Amsterdam Casualty Co. v. Johnson, L.R.A., 1916, B. 1018, that the injury will not be considered as the result of an accident, where, under the circumstances attending the dilatation, there is no evidence that anything occurred which the insured had not planned or anticipated, excepting, of course, the dilatation and its consequences.

False Statements in an Insurance Application.—Where the secretary of an insurance order knew of the falsity of statements as to physical health contained in a member's application, and the medical examiner must have discovered their falsity, yet the insurer, for over two years having continued the membership and accepted the premiums, was held, by the Colorado Supreme Court, to be estopped in an action on the certificate to set up the falsity of the statements in the application.—McRory v. Independent Order of Puritans (Colo.) 154, Pacific 92.

Book Reviews.

Hay-fever. Its Prevention and Cure. By W. C. Hollopeter, A.M., M.D., LL.D., Attending Physician St. Joseph's Hospital; Pediatrician to the Philadelphia General Hospital; Professor Pediatrics, Emeritus, Medico-Chirurgical College; ex-President of the Association of American Teachers of the Diseases of Children; ex-Chairman of the Section on Diseases of Children, American Medical Association; Member of American Academy of Medicine, etc. Price, $1.25 net. New York and London: Funk & Wagnalls Company, 1916.

After careful perusal of this work, it is found that the neurotic element is still considered to play a large part in the causation of hay fever, and that a keen mentality in the victim likewise seems to be a happy coefficient. Dr. Hollopeter may therefore have high hopes that between sneezes and the carrying out of his many-sided and detailed treatment, the patient may have the opportunity to read about the numerous theories of hay-fever to be found in this volume of 347 pages.

Judged from the medical standpoint the book shows the work of years, for it is practically a compilation of each and every theory and mode of treatment that has ever been advanced for hay-fever. The majority of theories and treatments are stated in the words of the originators, which means an enormous amount of quotes in the text; but this rather adds to the value of the book. While the author's own theory and mode of treatment cover but a small portion of the text, they are so definitely stated that one cannot fail to comprehend them. The bibliography, extending from the years 1565 to 1916 and covering forty pages, is another valuable contribution to hay-fever literature. The book is beautifully printed, but somewhat loosely bound. The cover is a work of art being of a soothing, dark green color, and having *gold* golden rod as a decoration. If the psychic element plays such a strong rôle in the production of hay-fever, was it not a daring stroke to put this beautiful, but dangerous weed where it must meet the eyes of the suffering victim?

When one has finished the book there is a realization that it is well-written, well-compiled. The author's treatment includes local—upon which he lays great stress—systemic, and hygienic measures. He adheres strictly to medicines in his local treatment and has nothing to do with the pollen or bacterial vaccines, or autoserums. However, a feeling of disappointment creeps over one that after all Dr. Hollopeter's book brings out the fact, perhaps unconsciously, that there is no cohesion in the various treatments of the different theorists, each one working out his ideas irrespective of the theories of other workers in the field. Will there ever come a physician who will be broad enough to give a thoughtful combined treatment to the same patient, both pollen and bacterial vaccine, and at the same time investigate his intestinal, nasal, and nervous conditions? The intestinal theorist will have none of the vaccines, the laboratory man refuses the medicinal or surgical aids, and the internist relies solely on his drugs. It it not to be wondered at that each stickler for his pet theory can hope to cure only a certain proportion of hay-fever victims.

Handbook of Massage for Beginners. By L. L. Despard, Member and Examiner, Incorporated Society of Trained Masseuses. Price, $2.00. New York: Oxford University Press, American Branch, 1915.

Despard's book is a very satisfactory one. The war and the consequent rapid pressing into service of those previously untrained in massage has been the immediate cause for the publication of the book. It is frankly a shortened and simplified edition of his text-book, and is intended for those who have time or opportunity for only a short course of training. All the study of anatomy included in the text-book is omitted. The various movements and manipulations of massage are well described and excellently illustrated. The immediate and indirect effects of massage are explained and the values of their effects to the general economy. After presenting the subject from a general standpoint, Despard gives the special treatment indicated in various special conditions. The manipulations and exercises are properly balanced, and reasons for choice of movements and their order are given, so that the student has continual emphasis laid in the condition which he is attempting to improve. The last forty pages are given to an exposition of medical electricity. This is very clear and goes into enough detail in regard to electricity, so that the student should handle the apparatus with intelligence. Strength of current and length of treatment to be given for various conditions are stated.

Hysteria and Accident Compensation. Nature of Hysteria and the Lesson of the Post-litigation Results. By Francis X. Dercum, M.D., Ph.D., Professor of Nervous and Mental Diseases, Jefferson Medical College, Philadelphia; Consulting Neurologist to the Philadelphia General Hospital; President of the Philadelphia Psychiatric Society; ex-President of the American Neurological Association and of the Philadelphia Neurological Society; Foreign Corresponding Member of the Neurological Society of Paris, and of the Neurological and Psychiatric Society of Vienna; Member of the Royal Medical Society of Budapest, etc. Philadelphia: The George T. Bisel Company, 1916.

In the light of the present interest in workingmen's compensation, Dr. Dercum's extremely interesting book is of especial value. Dr. Dercum is in position to have first-hand knowledge of the "litigation hysteria" of which he writes. He holds that the hysterical person is "born, not made," that injury and fright are not responsible for the hysterical condition for which compensation is sought, since these conditions do not arise and persist unless there is the possibility of obtaining compensation. He says that "fright hysteria is of immediate onset, its symptoms supervene at once at the time the fright is experienced, and as a rule it is of short duration and usually rapidly subsides. . . . Very frequently the history of the hysteria of litigation is that of a slow and gradual development," really developing under the hands of the lawyer and medical experts who are called in to determine that he should have compensation. Dr. Dercum says that the final proof of the fact that litigation is the determining factor is the rapidity with which recovery without treatment takes place after settlement is finally made. His conclusion is sound: "To deny compensation would seem to be the only way in which the question can be solved. If it be not possible to recover for litigation hysteria, litigation hysteria will have no existence. To deny compensation has already been advocated in Germany, and in France one of the courts, in a given case, declared that the plaintiff was suffering not from the accident alleged but from an erroneous opinion which he had formed as to the rights to which he was entitled, and ruled that he could not recover."

Year-Book of Pharmacy. Comprising Abstracts of Papers Relating to Pharmacy, Materia Medica, and Chemistry, Contributed to British and Foreign Journals from July 1, 1914, to June 30, 1915, with the Transactions of the British Pharmaceutical Conference at Its Fifty-second Annual Meeting, Held in London, July 14, 1915. Editor of the Abstracts, J. O. Braithwaite. Compiler of the New Remedies Section, Thos. Stephenson, F.R.S.E. Editor of the Transactions, Reginald R. Bennett, B.Sc., F.I.C. London: J. & A. Churchill, 1915.

The index of this work contains about 2,500 titles, including subjects and proper names. All the British Pharmacopœia revisions are comprised in a special section. Of the 400 pages of actual text about one-half are devoted to excerpts on chemistry and over one-fourth to pharmacy. The section on New Remedies and New Uses of Old Remedies is very brief. Under the heading "Notes and Formulæ" we find many non-proprietary cosmetics. American special literature is well represented, while abstracts from German litera-

Précis de Médecine Opératoire. Par A. Broca, Professeur d'Operations et Appareils à la Faculté de Médecine de Paris. Avec 510 figures dans le texte. Prix, 9 francs. Paris: Masson et Cie., Editeurs, 1916.

This work is of a very old type, comprising solely the technique of ligation of vessels, amputations, and disarticulations. The number of pages is less than 300, and all the illustrations are in the text. It is virtually an atlas, and one, moreover, of pocket size and flexible covers. It seems singular that the preface contains no reference whatever to the present war or to military surgery. One must, however, read between the lines that, despite the absence of any authorization from the government, such a work would be extremely timely for thousands of physicians at the front, who are operating without special training. If an authorized work of this type is not already in use in the army, we venture the prediction that the latter will be made official. Its excellence is quite beyond criticism.

Society Reports.

ASSOCIATION OF AMERICAN PHYSICIANS.

Thirty-first Annual Meeting, Held in Washington, May 9, 10 and 11, 1916.

THE PRESIDENT, DR. SEWALL OF DENVER, IN THE CHAIR.

(*Concluded from page* 264.)

Thursday, May 11—Third Day.

The Effects of Exposure to Cold upon Experimental Infection in the Respiratory Tract.—Drs. JAMES ALEXANDER MILLER and WILLIS NOBLE made this contribution. They stated that a widespread medical belief was that exposure to cold was an important factor in the incidence of many diseases. Since the development of modern bacteriology the importance of this factor had gradually diminished and at the present time there was considerable difference of opinion as to whether such exposure played any part whatever in the causation of disease. Experimental evidence was conflicting and as a great many of the animal experiments had been conducted with pneumococcus with which there had been considerable difficulty in producing experimental disease with regularity in animals, the results were not conclusive. The present experiments were carried out with rabbits inoculated with *Bacillus bovisepticus*, which was an organism which caused the well known laboratory disease in rabbits commonly designated as "snuffles." It was selected for experiment because these conditions produced in rabbits were so similar to those caused by some of the respiratory infections in man, particularly pneumococcus, and because of the relative difficulty of producing pneumococcus pneumonia in rabbits. The experimental animals were kept in a warm temperature for periods of time varying from twenty-four hours to a week and were then inoculated by spraying the nose and throat with virulent cultures of the "snuffles" bacillus. They were then immediately chilled by exposing them to outside weather, the temperature of which was 45° F. and lower. The experiments were carried out in the winter of 1914 and 1915 and another series in the winter of 1915 and 1916. The totals for both series showed that of 37 experimental animals 15, or 40.5 per cent., reacted to the infection, while of an equal number of controls, nine, or 24.3 per cent., reacted. The striking difference between the two groups in the first year's experiments led very strongly to the belief that the exposure must be an important contributing factor. The second year's series, although a much smaller number, distinctly modified the strength of this opinion, as an equal number of experimental and control rabbits reacted to infection in this series. Taking both series together, however, the conclusion seemed justified that exposure to cold after previous subjection to warm temperatures rendered rabbits somewhat more liable to infection with the *Bacillus bovisepticus*.

On the Expectorant Action of Ammonium Chloride.—Dr. WARREN COLEMAN of New York presented this paper. He said that experiments had been made on the action of ammonium chloride on dogs, but there were a number of factors influencing results which could not be properly controlled in animal experiments with reference to the expectorant action of drugs, so he determined to try the effects of this drug on human beings. His subjects were a house physician, a nurse in training, four other physicians and himself. With the first subject he began with 0.02 mg. and increased the amount up to 0.05 mg. In a second subject he went up to 0.06 mg. He himself took the drug in one-half grain doses every two hours, the last dose between seven and eight o'clock at night, and he found that the next morning the taste of the drug would appear. This had a two-fold significance. It identified the form in which the ammonium nitrogen was present and its relation to the conversion of ammonium chloride in the liver. It seemed that the ammonium chloride left the body in the form that it entered. It also had the effect of relieving the soreness and dryness of the respiratory tract. As to its action a plausible explanation was that it carried water with it and thus softened the mucous and that a softening action was due to the salt also, and that with a softening of the mucous membrane the normal mechanism of secretion came into play.

Dr. ABRAHAM JACOBI of New York said that as a matter of history he would like to take the liberty of telling them that when he had lectured before the students of the College of Physicians and Surgeons, not fifty years ago, but some time ago, he told them that ammonium chloride was an inert drug, that it did not have as stimulating an action as the carbonate. In Germany physicians used to give as a placebo, when they were unable to make a diagnosis, a prescription calling for two drams of ammonium chloride and two drams of licorice. He used ammonium carbonate in chronic bronchitis with viscid secretion and found it would do something toward liquifying the secretions.

Dr. SAMUEL J. MELTZER of New York said he believed they had two kinds of expectorants. One kind increased the secretions and the other was the cause of irritation, and one prescribed one kind or the other according to the action desired. What Dr. Jacobi said with reference to ammonium carbonate must have been a slip. Ammonium carbonate does not have the action he had attributed to it. It should be remembered that drugs did not always act directly, that they sometimes had a catalytic action. They underwent changes, entered the circulation and in that way produced a local effect. The experimental study of medicine was absolutely necessary and the only good evidence was that of man himself. These personal experiments were practical, but one must have the faculty of observation and of analysis.

Dr. MAX EINHORN of New York said he was delighted to hear Dr. Coleman say that he had tried this drug on human beings to see what effect it produced. That was the right way to proceed. Trying it on himself was better than trying it on anyone else. In his experience in the treatment of gastric conditions he had found ammonium chloride of great benefit.

Dr. COLEMAN in closing the discussion said that in reply to Dr. Erlanger's question as to whether the ammonium chloride appeared to be in the sputum or the saliva, they were planning experiments in which they would furnish specimens of the saliva and of the sputum and investigate the matter. As for himself he never got the taste of the ammonium chloride from the saliva, but only in the sputum from the bronchial tubes. As to the stage of the disease when the drug was effective, he found that it gave relief when there was dryness with irritation and a non-productive cough. As to whether the effect of the drug was brought about by a central or a peripheral action, he believed its action depended upon its elimination by the bronchial mucous membrane, but did not believe it had any action upon nerve centers.

Coagulation Time in Lobar Pneumonia, with Statistics and Experimental Study of the Coagulation Process.—Drs. J. M. ANDERS and GEORGE H. MEEKER of Philadelphia presented this communication. They stated that undoubtedly microorganisms did have an influence upon the coagulation time of blood but their true significance was undecided. It had been said that acute infections tended to retard the process of coagulation. They made their tests on blood taken from the lobes of the ears and the finger tips both before and after the crisis in pneumonia. The blood was taken one and two hours after meals. They found that the coagulation time was somewhat shortened, on a mean average, of about two minutes. The hypothesis was suggested that the pneumococcus circulation in the blood might liberate thrombokinase from the walls and that this gained access to the circulation. There was no laboratory evidence that could be accepted as proof of this. Dr. Anders said that he believed that the percentage of leucocytes circulating in the blood might be the cause of the somewhat shortened coagulation time of the blood in this disease. It was possible that prothrombin was liberated more rapidly and had an effect upon the coagulation time. This theory lacked support, since it had not been shown that there was an increase in the calcium salts in the blood in pneumonia. Dr. Meeker had made quantitative study of the amount of calcium salts in the blood of pneumonia patients and found that the amount of calcium in the blood of these patients was practically the same as that in leutic infection. They concluded that the coagulation time of the blood was shortened in lobar pneumonia; that the influence of pneumonia on the coagulation time, though trivial, was constant and that from their experiments in regard to the calcium content of the blood in pneumonia the influence of the calcium salts must be quite considerable.

Dr. SAMUEL J. MELTZER of New York said he wished to mention that in experimental pneumonia there was a difference in the amount of calcium in the blood in the virulent and the non-virulent forms of the disease.

In the non-virulent form there was not much calcium.

Dr. RUFUS I. COLE of New York called attention to some observation published by Dochez in which he showed that there was much increase in fibrogen in the blood in pneumonia and yet the coagulation time was delayed. Where there was a large amount of calcium in the blood we could not have this phenomenon.

Dr. MAX EINHORN of New York asked Dr. Anders if he had watched the amount of sodium chloride retained in the blood and the elimination through the kidneys. The sodium chloride retention might have some effect on the coagulation time of the blood.

Dr. ANDERS said that since seeing these experiments he felt that in the case of pneumonia they encountered a paradox, it seemed that the coagulation time was shortened, yet they knew that after death the large vessels were occupied by large thrombi and this would indicate that post mortem the coagulation went on slowly.

A Study of the Action of Certain Diuretics in Chronic Nephritis. — Dr. HENRY A. CHRISTIAN of Boston said that on this occasion they would report on the action of theocin. He said that a considerable number of drugs considered to be active diuretics had been shown to shorten the life of animals with severe nephritis and that as a consequence our faith in active diuretic drugs was decreasing. He described the experiments that he had made by means of a series of charts. The first four of these charts showed the effect of theocin on active nephritis as regarded the sodium chloride excretion, and nitrogen urea, and diuresis. He concluded that as a rule theocin produced a marked diuresis in inverse ratio to the degree of renal function. Often when there was an active diuresis there was a decrease in renal function, probably indicating fatigue and suggesting that it was better to give a diuretic intermittently rather than continuously. Another point that was brought out was that one might have an active output of urine but no increased output of nitrogenous substances. So that it was a question how much the drug affected the patient where there was no uremia. In uremia which had a definite relation to the retention of nitrogenous substances it was a question how much effect diuresis had towards detoxifying the patient. In some patients there was no diuresis and no increased output of nitrogenous substances; in these there was a decreased renal function and in these cases the drug was probably really harmful. Basing their opinion on their observation of acute and chronic nephritis and cardiorenal diseases as influenced by diuretic drugs the indications were that one should exercise great caution in the use of diuretic drugs.

Dr. WILLIAM S. THAYER of Baltimore said he considered this quite an important piece of work and one quite in accord with his clinical experience. In cardiorenal disease where the heart begins to fail diuretic might be indicated, but in chronic renal disease the administration of diuretic was a dangerous and serious procedure.

Dr. JAMES M. ANDERS of Philadelphia said that this paper had a very practical bearing. On cases of kidney impermeability with more or less cardiac involvement, one should make the phthalein test for renal function and if one found a degree of renal function of less than 30 per cent. in two hours one should avoid the employment of a laxative containing members of the purin group. To promote the elimination of poisons in such cases as Dr. Christian had described large draughts of water might be used. He felt sure that water employed in this manner often changed the scales in the direction of improvement.

Dr. CHRISTIAN in closing the discussion said that as to the phthalein test as an indicator of the degree of kidney function we should distinguish between the output due to chronic passive congestion and that due to renal insufficiency. In passive congestion one might use a diuretic and digitalis and a low phthalein output was no contraindication if one used the diuretic combined with digitalis. As to water a large intake of water shortened the life of animals with very acute nephritis; this subject had been studied very little and what was obviously needed was a study of the effect of water on the renal function.

Toxic Effect of Urea on Normal Individuals.—Dr. A. W. HEWLETT, Drs. GILBERT and WICHETT of Ann Arbor, Mich., contributed this paper in which they recorded their observations with reference to the effects of the administration of urea on animals. They found that to get effects they had to introduce large amounts of urea very much beyond the amount that was present in clinical uremia. Doses of 100 grains every few hours were given until the urea in the blood rose to the level of that in the blood of uremic patients. There was likewise a rise in the Ambard coefficient to nearly double what it was before the administration of the urea. When there was 75 per cent. urea nitrogen per 100 c.c. of blood the symptoms began to show themselves by headache, dizziness, prostration, drowsiness. They had what was known as the asthenic type of uremia. There was no vomiting, the appetite was good and there was no rise in blood pressure. There was a tremendous output of urea in the urine, but in 24 hours the larger part of the urea that had been administered was out of the body. From these observations it seemed that urea might be a cause of asthenic symptoms.

Dr. WARREN COLEMAN of New York cited a case which seemed to indicate that to some extent urea might be a factor in the production of uremia, but said that there were other cases in which it could not enter as a factor.

Experimental Endocarditis, Its Production with Streptococcus Viridans of Low Virulence.—Drs. H. K. DEFWEILLER and W. L. ROBINSON or Toronto made this presentation by invitation. They stated that the cultures of streptococcus viridans obtained from the blood from cases of chronic endocarditis reported a year ago had been inoculated into a series of rabbits and endocarditis was produced in a number of cases. The inoculations were all intravenous and consisted of enormous quantities of the organisms suspended in saline. The autopsy findings led them to believe that this organism had a special affinity for the heart, and especially for the heart valves. Evidence was forthcoming to show that the streptococcus viridans obtained from the normal mouth was equally productive of heart lesions, and any grade of endocarditis might be produced by any one organism, depending upon the amount injected, the number of injections, and the length of time between the first inoculation and the death of the animal.

Blood Sugar Estimations as a Test of Carbohydrate Tolerance.—Dr. LOUIS HAMMAN of Baltimore read this paper. He stated that frequent examinations of the blood and urine after the administration of glucose to fasting persons revealed four types of reaction. The normal reaction was a rapid rise in the blood sugar to a level not exceeding 0.15 per cent. From this point it again rapidly declined, the whole reaction being over in less than two hours. In the diabetic the blood sugar rose more slowly but reached a higher point, 0.2 per cent. and over. The high point was maintained for some time, and the decline occurred gradually, the whole reaction lasting three hours and longer. If the blood sugar rose above 0.175 per cent. sugar appeared in the urine. The third type of reaction was the renal reaction. This occurred in a small number of persons, in whom, although the blood sugar curve was in all other respects like the normal reaction, still sugar appeared in the urine. In severe cases of diabetes this same low thread shape was often found. In the fourth reaction, the nephritic, the blood sugar rose to a high level, often exceeding 0.2 per cent., and the blood sugar curve resembled the diabetic reaction: however, no sugar or only a trace of sugar appeared in the urine. The writer concluded that the blood sugar reaction after the administration of glucose and relation to glycosuria gave valuable clinical data in diabetes and in other conditions.

The Vital Capacity of the Lung and Its Relation to Dyspnea in Heart Disease.—Drs. FRANCIS W. PEABODY and A. WENTWORTH of Boston read this paper in which they showed that the production of dyspnea in patients with heart disease depended in part, at least, on inability to increase the minute volume of air breathed to as great extent as the normal person. This was due to a decrease in the vital capacity which limited the depth of breathing. The tendency of a patient to become dyspneic on exertion varied closely with the degree of the decrease in vital capacity. The determination of the vital capacity gave an indication of the amount of exercise which would produce dyspnea, and was a guide to the severity of the functional disability of the case.

Gastrohydrorrhea in Cirrhosis of the Liver Accompanied by Pyloric Stenosis.—Dr. MAX EINHORN read this paper. The term "gastrohydrorrhea," he said, signified the flow of a watery fluid from the stomach containing neither hydrochloric acid nor rennet or pepsin ferments. Such a flow to the amount of one to one and a half quarts a day was encountered in a patient suffer-

ing from cirrhosis of the liver accompanied by a pyloric stenosis. No ascites had developed. At autopsy a typical cirrhotic liver and a pyloric tumor (cancerous) were found. The gastrohydrorrhea was explained by a transudation process relieving the venous congestion in the stomach and was akin to an accumulation of ascitic fluid from the intestines in cirrhosis of the liver without pyloric obstruction.

The Immunizing Effect on Swine of Desiccated Sensitized Hog-Cholera Virus.—Drs. C. W. DUVAL and M. J. COURET of New Orleans state that the method hitherto used of preparing a sensitized virus for hog-cholera had been expensive, involving the sacrifice of two animals. They had devised a method by which the virus can be prepared with a smaller quantity of blood and which is equally effective. They gave one-fourth to one mg. as a first dose and repeated it three weeks later by a dose of five to ten mg. This conferred immunity for at least ten months. Some of the animals immunized with this virus had withstood large doses of virulent virus at the end of ten months.

Action of Opium Alkaloids and Their Combinations on the Vomiting Center.—Dr. DAVID L. MACHT of Baltimore related his experience with the opium alkaloids. He said that the opium alkaloids, morphine, codeine, papaverine, etc., might be divided into two groups. Morphine produced vomiting when administered in small doses and the others did not, so morphine was in a class by itself and the others formed a second group. He had tried administering these drugs in various ways, subcutaneously, intramuscularly, intravenously and the only one that produced vomiting was morphine. If apomorphine was given after morphine no vomiting was produced because the apomorphine paralyzed the vomiting center. The remarkable phenomenon in connection with the administration of combinations of these drugs was that they did not produce vomiting. On the average a combined dose of morphine and one of the others of 0.5 of a grain did not produce vomiting, but a dose of 0.3 of morphine did produce vomiting. They had found that 5 mg. or 1/12 grain of morphine produced vomiting in some instances whereas as much as 20 mg. of pantopon could be given without any nausea. The writer offered an explanation of the difference in the action of morphine and the other alkaloids of opium based on the fact that they were members of different chemical groups.

The Rôle of the Liver in Acute Pylocythenia. — Dr. PAUL D. LAMSON of Baltimore, Md., presented this contribution. He recorded his experiments by which he had tried to find the course of the increase of red blood cells in polycythenia. They produced experimental polycythenia in animals by huge doses of epinephrin and then by removing various organs tried to find which one was responsible for the increase of the red cells. There were two theories to account for the increased red cells. One was that they were tucked somewhere in the body and the other that the increase was a result of the division of cells. No signs of new cell formation had been found. After excluding all the other organs as the possible source of the increased red cells he had tied off the circulation of the liver and found that the liver was the organ responsible for the increase of red cells in polycythenia. Thus far they were unable to give an explanation of the process by which this increase was brought about.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting—Held May 4, 1916.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

An Explanation of Some Disorders Supposed to Have an Emotional Origin. — Dr. WALTER B. CANNON, George Higginson Professor of Physiology, Harvard Medical School, Boston, Mass., delivered this address, in which he said that during the past four or five years many of the researches of the Harvard Physiological Laboratory had been concerned with the bodily changes which accompanied strong emotions, such as fear and rage. These were fundamental experiences in man and the lower animals, so much so that their expression constituted a sort of common language. The studies which had been carried on had revealed interesting relations between these emotions and certain glands of internal secretion, and had suggested also a way in which emotional excitement might occasion pathological states. When a cat became infuriated, the pupils were dilated and the hair was erect from the neck to the end of the tail. But besides these surface manifestations there were internal changes; for example, the heart beat rapidly and the activities of the stomach and intestines were stopped. Both the internal and the external changes were due to the passage of nerve impulses to viscera along the neurones of the sympathetic division of the autonomic system. The relation of the fibres connecting the central nervous system with these neurones was such as to provide for diffuse action on all the viscera that were innervated by this division. The adrenal glands were supplied with nerves from the sympathetic division; and also the secretion of the adrenal medulla affected all structures innervated by the sympathetic division precisely as if they were being stimulated by its impulses. They had found that the adrenal glands secreted adrenin in times of great excitement, that there was an increased liberation of sugar from the liver so that glycosuria might result, that there was an abolition or prompt lessening of muscular fatigue, and that there was a very much more rapid clotting of blood. It was known also that adrenin caused a redistribution of blood in the body so that it was sent away from the alimentary canal whose activities were inhibited, to the heart, the lungs, the central nervous system and active skeletal muscles. It was known, also, that adrenin caused dilation of the bronchioles and it was known that it increased the number of red blood corpuscles per cubic millimeter—an increase which Lamson had shown occurred also to a marked degree in cases of emotional excitement. These changes, as true of man as of the lower animals in times of great emotional stress, were significant when the conditions which would give rise to the emotions were considered. Fear was associated with the instinct to flee; rage with the instinct to fight. These were the emotions and instincts underlying the struggle for existence. They were also the emotions and instincts into which all other instincts might be readily turned when they were thwarted. The internal changes were all directed towards increasing the efficacy of the organism for physical struggle. The increased blood sugar provided a source of muscular energy. The altered distribution of blood and the increased number of red blood corpuscles arranged for carrying an abundance of oxygen to the active structures. The dilated bronchioles allowed ready ventilation of the lungs when oxygen was greatly needed and carbon dioxide was being produced in large amounts. The provision for lessening muscular fatigue was directly useful in muscles likely to be employed in continued action. The rapid coagulation of blood tended to preserve that precious fluid in case of injury to blood vessels. The organism in which these changes most promptly occurred had the greatest reinforcement of its abilities and was most likely to be favored in physical struggle. These arrangements for reinforcement accounted for the great power and endurance which were exhibited in times of intense excitement. Other glands than the adrenal were not so readily studied because of the difficulty of recognizing their secretions. It had long been known, however, that physiological activity was accompanied by the presence of an electrical difference which might be observed by connecting an active part with an inactive part of the body through a sensitive galvanometer. Justification of this method of studying glands could be obtained by applying it to the submaxillary gland. It had been found that the electrical change began before the external secretion appeared, disappeared as secretion stopped, and was not related either to flow of fluid in the ducts or a change of blood flow in the capillaries. Since the only feature that could not be abolished without abolishing the electrical change was secretion, the electrical effect was a true indicator of a secretory process. When this method, therefore, was applied to the thyroid gland, the positive testimony of the galvanometer was evidence of thyroid secretion. The electrical method showed that the thyroid gland was subject to impulses from a part of the sympathetic division of the autonomic system, i.e. the cervical sympathetic. The secretion came promptly—after a latent period from 5 to 7 seconds. The vagus nerve was without control, and pilocarpine, as a stimulator of vagus endings, was likewise without control. The influence of the sympathetic was not due to anemia, for shutting off the blood supply had no such effect as was produced by sympathetic stimulation. Control by the sympathetic implied that adrenin might be effective in stimulating the thyroid. This, in fact, was the case, for a marked electrical change was produced when adrenalin (0.1 c.c. of 1:100,000) was in-

jected intravenously into a cat. Furthermore, the action current of the thyroid appeared if the nerves to the adrenal gland were stimulated, an effect which did not occur if the adrenal glands had been previously removed and which was delayed if the return of blood from the abdominal cavity was delayed until the blood was again allowed to flow. Thus a hormone relation between the adrenal and the thyroid was clearly demonstrated. This electrical evidence, which was obtained in cooperation with Dr. J. McKeen, Cattell, had been confirmed by the observations of Dr. Robert L. Levy. He had found that both stimulation of the cervical sympathetic trunk and injection of stimulating doses of adrenalin greatly augmented the effects of small doses of adrenalin in raising blood pressure. This increase of efficacy of adrenalin was not produced if the thyroid glands had previously been removed. The proof that the thyroid responded rapidly to sympathetic stimulation and that it was effective in combination with adrenal secretion showed that there was another bodily change to be added to those already mentioned as occurring in times of great emotional excitement. In the course of this work two questions had arisen. First, why were organs which were disturbed in times of emotional stress not disturbed at other times? It seemed probably that they were protected from interference by a high neurone threshold interposed between the central nervous system and the visceral cells. Consequently only when great excitation was present in the central nervous system was this threshold crossed and the changes in the viscera brought to pass. The second question was, why, in certain pathological cases, was there apparently frequent or continuous disturbance of these same viscera? It seemed possible that this might be due to a wearing down of the high threshold here or there from frequent or great emotional experiences. Thus the situation would be like a break in a dike, and only a slight disturbance in the central nervous system might then be needed to result in a pouring through of impulses at the low point and consequently a fairly frequent or continuous disturbance in the viscus innervated by this region. Thus dyspepsia, tachycardia and probably persistent glycosuria, reported as having an emotional origin, might be accounted for. To test the effect of continuous stimulation the phrenic nerve was fused with a peripheral portion of the cut cervical sympathetic. This operation, done with the aid of Dr. C. A. L. Binger, resulted in some animals in tachycardia, increased excitability, loose movements of the bowels, exophthalmus on the operated side (in one case) and, as Dr. Reginald Fitz showed, in great increase of metabolism (in one case an increase of 130 per cent.). These phenomena had disappeared on removal of the thyroid gland on the operated side. The adrenal glands in two animals that had died of the disease had been greatly enlarged. The changes thus produced resembled in many respects the symptoms of exophthalmic goitre and supported the view that this disease might be primarily due to overactivity of that part of the nervous system disturbed in emotional excitement,—possibly, as suggested above, a local stimulation in the cervical region. Two vicious circles might be operative: one through the nervous system due to increased excitability from increased thyroid secretion and resulting thus in increased nervous stimulation of the gland; the other through the blood stream due to increased adrenal activity from overaction of the thyroid and stimulating the thyroid in turn in the manner indicated above. The evidence previously presented showed that besides any routine function, the adrenal gland had an emergency function brought out in times of great excitement. It was not unreasonable to suppose that the thyroid gland likewise had an emergency function evoked in critical times, which would serve to increase the speed of metabolism when the rapidity of bodily processes might be of the utmost importance, and besides that augmenting the efficiency of the adrenin which would be secreted simultaneously.

Dr. Henry Rutgers Marshall opened the discussion by invitation. He said that he was led to his view as to the result of reading Charles Darwin's "The Expression of the Emotions in Man and the Animals," in which he conclusively showed that the activities commonly called the expression of the emotions were instinctive activities that had been inherited because of their racial value. This point was very effectively corroborated by Dr. Cannon's experiments. This was the view commonly held and as such deserved some study. For it was not at all clear on the face of it, how instinctive reactions, which always arose automatically, and immediately, upon the receipt of a definite stimulus could be caused by emotional states. Now, William James held, on the contrary, that the instinctive reactions caused the emotions, which were what Lloyd Morgan had aptly called "back strokes," which were resultant from the automatic instinctive reactions which we called expressions. To put the matter in the vivid language which Mr. James used, we did not flee because we were afraid, but we were afraid because we fled. We did not strike because we were angry, but we were angry because we struck. In other words, he held that the emotions of fear and anger, for instance, were after results of the purely automatic instinctive activities involved, directly or indirectly, with the running away, or with the striking of the enemy. In his more mature view the speaker said he had come to hold that the causal relation was not involved at all between the mental and the physical. All that the evidence pointed to was the existence of a strict one to one corresponding between the two. This was an important point, and Dr. Cannon's experiments seemed to corroborate it. Some of the results of such a view, both physiological and psychological, he had attempted to point out in an article published in the April number of *Mind*, in connection with the study of retentiveness, and of Bergson's and Freud's theories of dreams. Under such a view it would be seen that they no longer held that there existed a causal relation between the emotion and its expression; that they were no more warranted in saying with Professor James that they were afraid because they fled, that in saying with the common man, that they fled because they were afraid. All that one was warranted in saying was that the specific form of the instinctive reaction necessarily involved the equally specific form of the emotion, and *vice versa*. To put this in another way, what might be called an instinctive action was a relatively immediate reaction to a selective definite stimulus, and was based wholly, or in large part at least, upon inheritance. Man displayed a countless variety of such instinctive actions, varying greatly in complexity. The extreme limit in one direction was the simple reflexes, and the so-called emotional expressions were examples in the direction of complexity. Corresponding with the more complex instinct-actions changes were noted in the consciousness which might be called instinct-feelings. These differed as the instinct-actions differed. One felt such an instinctive feeling when quite automatically he rushed forward, and again when he jumped back suddenly to escape an automobile. And the instinctive feelings in the two cases were as distinctly different as the instinct actions were distinctly different. Now most of our instinct-actions recurred but seldom in anything like a definite form. Certain of them, however, did recur frequently, and were relatively constant in form. In such cases one came to recognize them and describe them as Darwin, and as Dr. Cannon had done. In like manner the corresponding instinct-feelings recurred for the most part, infrequently in any thing like a definite form; but some of them did, and these were recognized and given names. In the speaker's view it was the instinct-feelings of this latter type that were what we called the emotions. Thus it would be seen that this general conception taught us that a definite type of behavior necessarily involved a definite attitude of mind, and *vice versa;* and that each change of an individual's behavior necessarily involved a corresponding change of the individual's mental attitude; and *vice versa*. As nations were merely aggregations of individuals, this meant that definite changes of national attitude of mind must necessarily go with changes of national habits of action; a fact which, in the speaker's view, we were overlooking at the present moment. Perhaps this distinction might appear of little importance, but to him it seemed very important indeed. For, under the view which he had defended the emotions, as types of mental states, could not be looked upon as causally related with what we called their expressions; but merely as symptomatic accompaniments of these instinctive activities. It made all the difference in the world which position we took. For if we treated our mental states as causally related with physical states, the physician was tempted to step outside the real sphere of his work. While if we treated our mental states as symptoms of physical states, the mental states he employed merely and properly as aids to the discovery of such physical conditions as the physician was called upon to deal with. The speaker said he was especially interested in the

impressive evidence furnished by Dr. Cannon of the marvellously intricate coordination of minor systemic parts necessary to the very existence of the high organisms; evidence that had been accumulated in large measure in the last decades, and which led us to abandon the study of the physical organism as though it were a quasi atomic collection of separate organs; leading us rather to study it as was now being done, as a whole system of enormous complexity, in which each organic path had its place as a minor system. The biologist was thus coming daily to look upon problems relating to organization as of greater and greater importance, as was indicated, for instance, in the last book from the pen of the eminent English physiologist, Haldane. And correspondingly in the realm of consciousness psychologists had discarded psychological atomism and were treating the mind as an immensely complex system of psychic systems. This fact that the physiological and mental structure and functioning were to be considered as single wholes was surely often overlooked on the physiological side, for instance, by those pedagogues who urged intensive specialization in any particular field to the abandonment of broad culture. They forgot that this specialization tended to involve a loss of such balance of judgment as was required if real advance in thought was to be made. It had led in the scientific world to a great amount of pleading which passed without protest. The physician could be said to have escaped altogether the dangers involved in the forgetfulness of the fact that each part of the body was essentially related to the system as a whole. It was certainly overlooked if a surgeon operated where these was no urgent need, and where there was at the same time no little hope of a readjustment of functioning, by natural processes, which would leave the system intact and newly balanced. He seemed to observe this same forgetfulness when he heard his friends say, "My doctor tells me this drug will make me sleep, and has no after effects," or "My doctor says the medicine may help me and cannot in any event do me any harm." No one who was impressed with the import of the facts brought to their attention by Dr. Cannon could be guilty of such thinking, and he had dared make these critical remarks because he felt that they could not possibly apply to those present, except as they might urge them to take note of these things in the guidance of their pupils.

Dr. Charles L. Dana said that he was not a physiologist and he could not criticize but only accept Prof. Cannon's data. He accepted also as most reasonable the theory of the mechanism of defense which had been described. The speaker said that he subscribed to the laboratory work and the deductions presented by Dr. Cannon, and he did so in spite of a very critical attitude which he had begun to feel towards laboratories in general. They were doing splendid and constructive work, but they were also enslaving and in a way enfeebling the clinician; and they were sending out occasionally misleading and incomplete announcements. The laboratory often needed a humanizing influence, and should be more dominated by clinical spirit. He said that he had one practical suggestion to make bearing on Prof. Cannon's observations. There were emotional states which came on acutely, but lasted very intensely for weeks and months. These were cases of acute mania, or hypomania, in which the patient was joyously exhilarated, alert, talkative, had violent bursts of anger and was intensely active physically and mentally under the pressure of the emotional state, which some morning suddenly left him, or a contrary state of agitating depression occurred. These emotional states might be like those brought on by shock. The question whether they were brought on or kept up by periodical explosions of pluriglandular activity would be worth examining. We knew that in hyperthyroidism there was often a distinct excess of emotional tone.

Dr. Harlow Brooks spoke from the standpoint of the internist, and said there were two points that should be thus considered. First, how could they explain the influence of the emotions in the development of organic disease. In the clinical study of hypertension, of angina pectoris, and allied conditions, there was no clinician but realized the influence of the emotions in the development of organic disease. In the clinical study of hypertension, of angina pectoris, and allied conditions, there was no clinician but realized the influence of the emotions in the etiology of the disease In bronchial asthma, and in fact, the whole range of cardiac renal and vascular disease, they recognized this. This was one side of the question which touched the clinician. Secondly, there was another field which was more potent so far as clinicians were concerned, and that was in the treatment of disease. All recognized how much the emotions had to do with the patient's convalescence. Also the important condition of "lack" of over emotion in the care of certain conditions such as cardiac and renal diseases. He wished they could carry away with them the idea that it would be of great help to them if they would study more how the emotions controlled disease, how discipline and rest helped them to actually cure disease. By controlling the emotions, the habits, etc., they might be able to actually cure many of these conditions. He thought that they had been given this evening the explanation of many of the problems confronting them in every day practice.

Dr. Walter Timme said that he believed that emotional complexes had as reactions, disturbances of the normal state in the three nervous levels, the psychic, the sensori-motor and the vegetative. It was the vegetative that had engaged them at the present moment. As this vegetative level combined both the sympathetic and the extended vagus systems, and as these were interactive, it was hardly possible to consider one without the other. Emotions, such as anger, stimulated the sympathetic, but such emotions as depression, chagrin, or worry, stimulated the vagus and produced physiological changes which were constantly seen, notably, visceroptosis. One possible objection to Dr. Cannon's conclusions regarding the effect of the increased adrenalin in the adrenal veins of an animal that had been frightened, was that these same veins also depleted the adrenal cortex as well as the medulla. The adrenal cortex in human beings comprised almost nine-tenths of the gland, while the medulla which produced the adrenalin was only one-tenth. In animals the cortex was notably smaller proportionately than in human beings, and in acerebrate humans and idiots the cortex was almost entirely absent. It was noteworthy that with such absence the individual had much less inhibition of his emotional discharges in anger and fright. It might therefore be presumed that the cortex secretes a substance which was possibly antagonistic to adrenalin, and whose activity must be taken into account in such experiments as Dr. Cannon had described. An interesting problem was propounded in considering the mutual relations of adrenalin and the sympathetic system, namely, that they were mutually stimulating; that was, adrenalin irritated the sympathetic system, which in turn stimulated the adrenal gland to a future production of adrenalin. This newly formed adrenalin again effected the sympathetic with the secondary effect upon the andrenals, and so on, ad infinitum. And yet this was not so in fact, for it seemed that the adrenalin was immune to sympathetic stimulation produced by adrenalin. As for the interrelation of thyroid and adrenalin, he thought it had fairly well been proven that thyroid acted as a sensitizer to adrenalin just as it did to cocaine, enhancing its effects. In conclusion, he said their thanks were due Dr. Cannon for his elaborate work in establishing upon a firm basis what heretofore had depended upon empiricism. He had helped to transfer the entire system of internal glandular activity from the realm of the art of medicine to the realm of the science of medicine.

Dr. John Rogers remarked that none could doubt an emotional cause for many diseases, nor the physical effects of emotion. Excitement had often caused him while hunting to forget all sense of fatigue. Dr. Cannon had shown how emotion caused an increase in the circulation of adrenalin, or of the secretion from the adrenalin gland; also, that an increased activity on the part of the adrenal caused an increase in the activity of the thyroid. This was directly applicable to the clinical phenomena observed in Graves' disease. Here emotion or physical fatigue intensified the symptoms of over-activity of the thyroid. The adrenal gland was a very important part of the chromaffin or sympathetic nervous system. A few years ago no one had heard of the autonomic system; now it appeared that these two groups of nerves, or the sympathetic and autonomic, supplied every important organ in the body. They seemed to convey to each organ opposing influences. The autonomic fibers in the main appeared to convey secretory and motor impulses which some recently published experiments showed were activated by the products of several endocrine glands. This activation could apparently be inhibited by an extract of the whole adrenal gland or by adrenalin. This sug-

gested that normally there was a perfect balance between the adrenal or chromaffin, sympathetic system and the autonomous with their activating endocrine glands. When this balance was disturbed there arose the manifestations of disease. The adrenal was supposed to be supplied by the vagus which should have a secretory influence. Stimulation of the vagus stimulated the secretory activity of all the endocrine glands, including the adrenal. But the adrenal activated the sympathetic and so tended to inhibit the activity of the other endocrine structures. When this balance was disturbed there ought to arise the manifestation of disease, as above stated, and which now passed under the name of sympatheticotonic or vagotonic. Dr. Timme had hinted that adrenal was not the normal product of the entire living adrenal gland. If this suspicion proved true and adrenalin was some day found only in the stable part of some complex labile substance, it might then be possible to demonstrate the mechanism of the complicated diseases of which exophthalmic goitre was an example.

Dr. SAMUEL J. MELTZER said that he wished to assure Dr. Dana that Dr. Cannon had a very efficient clinician and physician associated with his laboratory in the person of Dr. Cannon himself. It had been most instructive and enjoyable to hear such closely packed facts as were contained in Dr. Cannon's address, all being the result of his own observations. He offered facts and when he offered theories they were a tight fit with his facts. Dr. Cannon's experiments pointed to the effect of the adrenals on the emotions of fear and hatred, but there was a further field for experiment in the discovery of the source of the softer emotions, such as the love of mothers for their children, for music, and for beauty. Perhaps those responsible for the fighting in Europe had very large adrenals. Dr. Cannon's animal used in experimenting on the harsher emotions was a cat. It was to be hoped that his choice of his next animal for experimentation further along these lines would rest on a pigeon, for instance, when he would perhaps find the controlling factor of the softer and desirable passions.

Dr. THOMAS DARLINGTON said that the presentation of facts gathered in laboratory experimentation was frequently so complicated by technical details as to cloud the main issue, and he felt that everyone shared his appreciation of the simple and lucid manner in which Dr. Cannon had clothed his address. It had been said at another meeting at the Academy that the greatest accomplishment of the laboratory was in aiding the practitioner to benefit and cure his patients, and it was certain that such experiments as Dr. Cannon's could be verified by any practitioner who realized that the first step toward a cure of disease was to relieve the mind of the patient of fear. As Oliver Wendell Holmes had said:

"Ah! sad and sick the suffering ones who miss
The touch and presence of a man like this,
Whose thrilling magnetism and cheerful laugh
Add to the remedies their better half,
And reinforce the courage and the will
And give sure virtue to the doubtful pill."

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

THE UNIVERSITY OF THE STATE OF NEW YORK.

May, 1916.

(*Concluded from page* 222.)

OBSTETRICS AND GYNECOLOGY.

1. Give the etiology of hemorrhage appearing externally after the birth of the child.
2. Describe the management of the third stage of labor in normal delivery.
3. What is placenta prævia? Give its varieties and its management.
4. What is concealed accidental hemorrhage? Give its etiology and its diagnosis.
5. Describe methods of examination of the female organs of generation.
6. What is the recognized normal position of the uterus? By what means is it retained in this position?
7. Describe the separation of the placenta.
8. What is erosion of the cervix? Give its etiology and its management.
9. What hygienic care should be observed at the period of puberescence?
10. What is accouchement forcé? When is it indicated?
11. Describe uterine polypi. Give their origin and their histologic composition.
12. What are the causes of venereal warts? Give treatment.

PATHOLOGY.

1. Describe ophthalmia neonatorum.
2. What portion of the uterus is the most common initial site of malignancy?
3. Give the technic of making a red blood count.
4. Give the pathology of erysipelas.
5. Give briefly the urinary findings, both chemical and microscopical, in chronic parenchymatous nephritis.
6. What changes take place in an inflamed part, causing redness and swelling?

BACTERIOLOGY.

7. Describe in detail how you would examine spinal fluid for meningococci, morphologically and culturally.
8. How would you determine whether or not a sore throat is caused by the diphtheria bacillus? Give details of procedure.
9. Describe a method of staining tubercle bacilli. How could you isolate the bacilli from chest fluid?
10. What is a typhoid carrier? How can it be ascertained bacteriologically that an individual is a typhoid carrier?
11. What is meant by active immunization? Give an example in which this principle is applied to the prophylactic immunization of man.
12. What is the principle underlying Pasteur's method of treatment of an individual who has been bitten by a mad dog?

DIAGNOSIS.

1. What are the symptoms of intracranial hemorrhage (apoplexy)?
2. Differentiate a syphilitic mucous patch from an aphthous ulcer of the buccal mucosa.
3. Describe the physical signs produced by pulmonary tuberculosis in its incipient stages.
4. Differentiate between aortic stenosis and mitral insufficiency.
5. Describe the renal conditions resulting from arteriosclerosis and give their symptoms.
6. Describe the symptoms and the clinical course of alcoholic cirrhosis of the liver.
7. Give the symptoms produced by deflections of the nasal septum.
8. In what disease conditions is there an increase in the number of leucocytes in the blood (hyperleucocytosis)? Mention *three* common disease conditions in which the number of leucocytes is stationary or lessened (leucopenia).
9. What symptoms indicate a perforation of the bowel in the course of typhoid fever?
10. What are the symptoms of myxedema and of what is it significant?
11. Mention *two* conditions in which wrist drop is an important symptom.
12. Describe the physical signs present in lobar pneumonia and the modifications to be noted in the different stages of the disease.

ANSWERS.

OBSTETRICS AND GYNECOLOGY.

1. *Postpartum hemorrhage.* Causes: Anything interfering with the firm contraction of the uterus after the expulsion of the child; retained placenta, or membrane, or clots; weakness of the uterine muscle; rapid labor; delayed labor; poorly developed uterine muscle; inflammation or disease of uterus; lacerations; imperfect separation of the placenta; mismanagement of the third stage of labor.

2. In the *third stage of labor* the physician should seize the fundus of the uterus through the abdominal wall and knead and rub it until it contracts vigorously; then he should press it down in the direction of the axis of the pelvic inlet. This should last for about a quarter of an hour after the child is born. The placenta, after it is expressed, should be carefully taken by the physician so as to be sure that it is *all* expelled; at the same time care must be taken that no particle of membrane remains behind. Fluid extract of ergot may be administered.

3. *Placenia prævia* is the condition in which the placenta is attached in the lower uterine segment and may be near or over (partially or completely) the internal os. *Varieties:* (1) *Central*, when the placenta completely covers the os. (2) *Partial*, when the placenta overlaps the os. (3) *Marginal or lateral*, when the placenta reaches the margin of the os but does not overlap it. *Treatment at term:* (1) Introduce one or two fingers within the os (the hand being in the vagina) and dissect the placenta from the uterine wall for about three inches from the os uteri in all directions, pushing it to one side if necessary. (2) Rupture the membranes, and if there is an unfavorable presentation, turn the child and make the breech engage in the os; or, if the head presents, the forceps may be used, if speedy delivery is necessary. Stop the hemorrhage by a tampon; this must be tight and thorough. *Accouchement forcé* is indicated; this consists of dilatation of cervix, version and immediate extraction of the child.

4. *Concealed hemorrhage* is one form of hemorrhage in premature detachment of the placenta. The blood dissects its way between the placenta and membranes, but does not escape externally (or only very slightly). *Cause:* Separation at center of placenta, the edges still being adherent; detachment of placenta at upper margin only; plugging of parturient canal and thus hemorrhage from any cause cannot escape. *Symptoms* are pallor, syncope, thirst, rapid and weak pulse; the uterus is soft and enlarged.

5. The patient should be free from corsets and constricting bands; the bladder and rectum should be empty. *External palpation:* The patient should be in the lithotomy position, on a suitable table or bed. The examiner stands on one side, and palpates the lower abdomen to determine any enlargement of the uterus. *Inspection* will show the presence of parasites, discharges, caruncle, chancre, condylomata, and lacerations. *Vaginal touch:* The examiner separates the labia with the thumb and finger of one hand; and two fingers of the other hand well lubricated are introduced into the vagina. Pressure is made on the perineum until the posterior fornix is reached, when the palmar surfaces are turned forward and the size, position, and condition of the cervix are determined. Then with the palmar surface of the external hand gentle pressure is made on the abdomen and the two hands are approximated. A *digital vaginal examination* will show: (1) The condition of the perineum, whether torn or not; (2) the size, shape, dilatability, temperature, discharges (if any) of the vagina; (3) the presence of cystocele, rectocele, prolapsed uterus, or other abnormal conditions of vagina; (4) position, shape, size, consistence of cervix, with presence of absence of erosions, lacerations (5) condition, shape, size, location, and mobility of uterus; (6) sometimes presence of abnormalities in tubes, and ovaries, and uterus (such as tumors, inflammations, etc.) *Rectal examinations:* In virgins and in some cases of extreme retroversion one finger is introduced into the rectum and with the other hand on the abdomen a more satisfactory bi-manual examination can be made. *Instrumental examination:* in the lithotomy position, by the use of a bi-valve, a tubular or Ferguson speculum, the condition of the cervix can be inspected. This is best accomplished in some cases by use of the Sims position and the Sims speculum. At the same time in rare and selected cases by steadying the anterior lip of the cervix with a bullet forceps the uterine sound may be passed to determine the size and position of the uterus.

6. The recognized normal position of the uterus is one of slight anteflexion, with its long axis at right angles to the long axis of the vagina. The anterior surface of its body rests on the bladder, and the cervix points backward toward the coccyx. The uterus is not fixed, but moves freely within certain limits. It is held in place by ligaments.

7. *Separation of the placenta* from the uterine attachment is due to the retraction and contraction of the uterus which brings about a disproportion between the placenta and its site: the attachments between the two are torn through. In the intervals between the contractions a moderate hemorrhage takes place behind the placenta, and this is a factor in bringing about the separation.

8. *Erosion of the cervix* is a condition in which the vaginal portion of the cervix uteri has on its surface a mucous patch consisting of a layer of columnar epithelium and newly formed glands; these replace squamous stratified epithelium. The condition was formerly described as an ulcer but a true ulcer is characterized by loss of tissue, and there is no loss of tissue in an erosion. The *causes* are unknown; erosions are found in virgins, nulliparous, and parous women. *Treatment* consists in cleanliness, mild astringent douches, cauterization of the cervix, general improvement of the health and surroundings of the patient; in severe cases Emmett's operation, and amputation of the cervix have been recommended.

9. *Hygiene of puberty:* "The period of puberty should be taken as extending not only over the few months required for the establishment of menstruation, but as including the time necessary for full physical development. During this time the energy of the girl is taxed by the rapidity of sexual development, by the great liability to circulatory disturbances, by the physical and mental strain of education, and by the conventionalities of society. The necessity, therefore, for great care is apparent. Nutritious and simple diet, frequent rest, moderate amusements, and adequate exercise are essential, Study, especially during menstruation, should never be pressed to the point of fatigue. Inasmuch as passional life now begins, and the whole nervous organization is therefore subject to new impulses and requirements, books and associates should be selected carefully, and whatever may unduly excite the emotions should be excluded. Errors committed now may have grave consequences, such as malnutrition, psychoses, sterility, menstrual and other functional disorders, and may make the woman a hopeless invalid. One of the most serious errors is premature marriage." —(Dudley's *Gynecology.*)

10. *Accouchement forcé:* "By this term is understood the forcible dilatation of the intact or partially dilated cervix, followed by version and extraction of the child. *Indications:* In this country the most usual indication for *accouchement forcé* is threatened or actual eclampsia. Occasionally it becomes necessary in concealed or accidental hemorrhage, and also in the rare cases of acute edema of the lungs, or broken cardiac compensation complicating pregnancy, as well as in certain cases of placenta prævia."—(Williams' *Obstetrics.*)

11. *Uterine polypi* are pedunculated tumors attached to the uterine mucous membrane. *Mucous polypi* "grow most frequently from the cervix. According to some authorities they occur only as a result of inflammatory changes, being a mere local hypertrophy and hyperplasia. These polpi vary from a pea to a hen's egg in size. They are made up of the elements of the mucosa and are very vascular, usually of a cherry-red color. Often more than one are found. They are covered with columnar epithelium; when growing near the os externum, they may be partly or, sometimes, entirely covered with stratified squamous epithelium. They are made up of spaces lined with columnar or cubical epithelium, lying in a delicate connective tissue stroma, rich in capillaries; often blood is found diffused among the fibrils. In some cases, where the spaces are somewhat distended, the lining epithelium may be considerably flattened. They contain thick or thin mucus. As these polypi grow and descend they dilate the cervix. Sometimes those growing in the body do not tend to work their way down through the cervix. They sometimes tend to recur; in some cases there is a malignant tendency. Sometimes these growths may have a covering of stratified squamous epithelium, through growing from the cervical mucosa."—(Webster's *Diseases of Women.*)

12. Venereal Warts. *Causes:* Gonorrhea, syphilis, irritating discharges, want of cleanliness, and (sometimes) the congestion and leucorrhea of pregnancy. *Treatment:* Excision of wart by curved scissors, followed by cauterization; application of calomel and salicylic acid; douches; cleanliness; tonics; and removal of the cause, if possible.

PATHOLOGY.

1. *Ophthalmia neonatorum* is an infectious, purulent inflammation of the conjunctiva in the newborn, due to the gonococcus or other pyogenic germ; produced by contact of the eye with the vaginal secretion of the mother during labor, or infected fingers, or instruments, etc.

The treatment is (1) *Prophylactic.*—Whenever there is the possibility of infection, or in every case, wash the eyelids of the newborn child with clean warm water, and drop on the cornea of each eye one drop of a 1 or 2 per cent. solution of nitrate of silver, immediately after birth. (2) *Remedial.*—Wash the eyes carefully every half-hour with a saturated solution of boric acid; pus

must not be allowed to accumulate. Two drops of a 2 per cent. solution of nitrate of sliver must also be dropped on to the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burned.

"The disease, if untreated, declines spontaneously, and the discharge almost ceases in about six weeks, the palbebral conjunctiva being left thick, relaxed, and more or less granular. Cicatricial changes identical with but less severe than those resulting from chronic granular lids, and analogous to those which occur in stricture of the urethra, sometimes follow; considerable permanent thickening of the ocular conjunctiva may also occur. There is a great risk to the cornea in this disease, partly from strangulation of the vessels, partly from the local influence of the discharge. If within the first two or three days the cornea becomes hazy and dull, like that of a dead fish, there is great risk that total or extensive sloughing will occur. In many of the milder cases ulcers form a little below the center and rapidly cause perforation. In other cases clear, deep ulcers form close to the edge of the cornea. There is less risk of ulceration of the cornea in the purulent ophthalmia of infants than in that of adults."—(Nettleship's *Diseases of the Eye.*)

2. The *cervix* is the most common site of malignancy of the uterus.

3. *To make a red blood count:* "The finger is cleansed and punctured. As soon as the blood is flowing freely a red-blood pipette is brought into contact with the drop, suction made, and the blood drawn up to the mark 0.5. In the case of an extremely anemic patient draw it up to the mark 1. If the mark is slightly over-reached, touch the point of the pipette against the towel till the column is brought back to the 0.5 mark. When the blood is drawn to the proper mark, and that on the outside of the tube wiped off (being careful not to touch the point), the pipette is immediately plunged into the diluting solution and suction made as soon as it is below the surface. This is drawn up until the mark 101 is reached. The pipette, held in the horizontal position, is tapped rapidly with the fingers in order to mix thoroughly the blood. Next blow out the diluting fluid and place a medium-sized drop of the diluted blood upon the small glass cylinder in the counting-chamber. The next step is the careful adjustment of the cover-slip over the drop of diluted blood. The drop should now nearly cover the central glass slide; there should be no air bubbles in it; it should not overrun the gutter. If the slide be held up to the light on a level with the eyes, a play of colored rainbow rings may be seen. This indicates that the technique has been correct. A few minutes should elapse before counting to allow the corpuscles to settle. The counting-chamber is exactly one-tenth of a millimeter deep. The ruled square used for counting reds is a square millimeter divided into 400 small squares, so that each small square is 1/400 square millimeter. Use the low dry lens, with most of the light shut off. It is well to adopt the rule of beginning with the lower right square and counting upward. Every fifth square above and to the left is subdivided by an extra line to facilitate the counting. The corpuscles lying on the upper and left lines are counted; those on the lower and right are not. Continue this upward course till five squares are counted, then take the next square to the left and go down five, then the next to the left and go up again five squares, and so on till the number of corpuscles in 200 small squares is counted. This sum is divided by 200, thus giving the number in each small square. To calculate the number of corpuscles per cubic millimeter, multiply by 100, because the blood has been diluted 100 times; then by 400, because each small square is one four-hundredths of a square millimeter; then by 10, as the square millimeter is only one-tenth of a millimeter deep. This gives the number of corpuscles in a cubic millimeter. In short, with a dilution of 1:100 the number of corpuscles in each small square is multiplied by 400,000. If the dilution has been 1:200, multiply by 800,000." (Arneill's *Clinical Diagnosis.*)

4. *Pathology of erysipelas:* "Sections of the affected skin reveal an infiltration with granular leucocytes and serum, often including many micrococci, and involving the subcutaneous cellular tissue and to a variable depth the fat. The leucocytes are most numerous in the capillaries and lymph-spaces of the outer zone, where the disease is advancing; they are also numerous around the hair follicles and sweat glands. Pus is formed in the worst cases. The edema is most pronounced in loose cellular tissue, as beneath the eyelids and the prepuce. Abscesses and infarction are occasionally found in the lungs, spleen, and kidneys." (French's *Practice of Medicine.*)

5. In *chronic parenchymatous nephritis:* "The quantity of urine is diminished, it is cloudy from urates; the specific gravity may be high in the early but is low in the later stages. Albumin is abundant, sometimes more so than in any other disease. The heavy sediment contains large numbers of nearly all the varieties of tube casts, hyaline, epithelial, granular, and fatty. The latter are especially characteristic. Occasional red corpuscles, many leucocytes, and numbers of degenerated epithelial cells are also found. The amount of urea is decreased." (Butler's *Diagnostics of Internal Medicine.*)

6. The *redness* is due to the hyperemia which is present in inflammation, the hyperemia being caused by the dilated vessels of the part.

The *swelling* is caused by the excess of blood present in the part, by the leucocytes brought to the part, by the exudate within the tissues, and by the newly-made tissue cells.

BACTERIOLOGY.

7. *To examine spinal fluid for meningocci:* The fluid should be received in a sterile container, and then centrifuged. The sediment is stained with Gram's stain; the diplococcus intracellularis meningitidis is a diplococcus, very small, with no capsule, non-motile, non-flagellate, Gram-negative, but staining by ordinary methods. A culture must be made very promptly; it grows at body temperature, on Loeffler's blood-serum mixture or glucose ascitic agar neutral to phenolphthalein. Transfers must be made frequently as the diplococcus is readily killed by heat, drying, sunlight, or disinfectants.

8. A sterile swab is rubbed over any visible membrane on the tonsils or throat and is then immediately passed over the surface of the serum in a culture tube. The tube of culture, thus inoculated, is placed in an incubator at 37° C. for about twelve hours, when it is ready for examination. A sterile platinum wire is inserted into the culture tube, and a number of colonies of a whitish color are removed by it and placed on a clean cover slip and smeared over its surface. The smear is allowed to dry, is passed two or three times through a flame to fix the bacteria, and is then covered for about five or six minutes with a Loeffler's methylene-blue solution. The cover slip is then rinsed in clean water, dried, and mounted. The bacilli of diphtheria appears as short thick rods with rounded ends; irregular forms are characteristic of this bacillus, and the staining will appear pronounced in some parts of the bacilli and deficient in other parts. *Methods of culture:* The bacillus of diphtheria grows upon all the ordinary culture media, and can be readily obtained in pure culture. Loeffler's blood serum, particularly with the addition of a little glucose, is an admirable medium for the rapid growth of this bacillus. The medium should be alkaline and not less than 20° C.

The *characteristics of the bacillus of diphtheria:* The bacilli are from 2 to 6 mikrons in length and from 0.2 to 1.0 mikron in breadth; are slightly curved, and often have clubbed and rounded ends; occur either singly or in pairs, or in irregular groups, but do not form chains; they have no flagella, are nonmotile, and aërobic; they are noted for their pleomorphism; they do not stain uniformly, but stain well by Gram's method and very beautifully with Loeffler's alkaline-methylene blue.

9. To demonstrate the existence of *tubercle bacilli* in the sputum: The sputum must be recent, free from particles of food or other foreign matter; select a cheesy-looking nodule and smear it on a slide, making the smear as thin as possible. Then cover it with some carbolfuchsin, and let it steam over a small flame for about two minutes, care being taken that it does not boil. Wash it thoroughly in water and then decolorize by immersing it in a solution of any dilute mineral acid for about a minute. Then make a contrast stain with solution of Loeffler's methylene blue for about a minute; wash it again and examine with oil immersion lens. The tubercle bacilli will appear as thin red rods, while all other bacteria will appear blue.

The chest fluid should be treated with antiformin, which kills most bacteria but not the tubercle bacilli; it is then centrifuged, and from the sediment the tubercle bacilli may be cultivated on blood serum. On account of the difficulty of obtaining material free from other bacteria (which grow more rapidly than the

tubercle bacilli), it is often necessary to inoculate guinea pigs subcutaneously with the sediment, and then obtain cultures from these animals as soon as the tuberculous infection has developed.

10. A *typhoid carrier* is a person who is not suffering from the disease, but whose excreta contain the typhoid bacilli and who, therefore, is capable of giving the disease to others. The finding of the typhoid bacilli in the feces (and urine) of such a person is proof of his being a typhoid carrier.

11. *Immunity*, or the power to resist invasion by microorganisms with the subsequent development of disease, is *active* when the cells or tissues of the invaded individual bring about this immunity, either by destroying the bacteria or by neutralizing their poisonous products. Such an immunity may be acquired in several ways; one is by inoculation, another is by vaccination; this latter is used as a prophylactic measure against smallpox.

12. *The principle underlying Pasteur's treatment for rabies:* "It consists of an active immunization with virus, attenuated by drying, administered during the long incubation period in doses of progressively increased virulence. By the repeated passage of street virus through rabbits, Pasteur obtained a virus of maximum and approximately constant virulence which he designated as *virus fixé*. He then ascertained that such *virus fixé* could be gradually attenuated by drying over caustic potash at a temperature of about 25° C., the degree of attenuation varying directly with the time of drying. Thus, while fresh *virus fixé* regularly caused death in rabbits after six to seven days, the incubation time following the inoculation of dried virus grew longer and longer as the time of drying was increased, until finally virus dried for eight days was no longer regularly infectious and that dried for twelve to fourteen days had completely lost its virulence. The method of active immunization which Pasteur used consisted in injecting, subcutaneously, virus of progressively increasing virulence, beginning with that derived from cords dried for thirteen days and gradually advancing to a strong virus. Thus the patient was immunized to a potent virus several weeks before the incubation time of his own infection had elapsed." (Hiss and Zinsser's *Bacteriology*.)

DIAGNOSIS.

1. *Symptoms of intracranial hemorrhage (apoplexy):* There may be prodromal symptoms such as vertigo, pain in the head, or impairment of memory; but as a rule the attack is sudden with vertigo and unconsciousness; there may be retention or incontinence of urine, the urine has a high specific gravity and may contain albumin; hemiplegia generally ensues; the tongue protrudes toward the affected side; asphasia (either motor or sensory) may be present; the face is flushed, breathing is stertorous; the body temperature is first subnormal and then elevated; the pulse is slow and full; in severe cases the pulse becomes weak, and the respirations become of the Cheyne-Stokes type; the reflexes are abolished.

2. *Apthous ulcers* are sharply defined, extremely sensitive, and evanescent in character.

Mucous patches are rounded or oval, flat, slightly elevated or depressed, grayish or pinkish in color, and slightly painful.

3. The early manifestations of pulmonary tuberculosis are: (1) *Physical signs:* Deficient chest expansion, the phthisical chest, slight dullness or impaired resonance over one apex, fine moist rales at end of inspiration, expiration prolonged or high pitched, breathing interrupted. (2) *Symptoms:* General weakness, lassitude, dyspnea on exertion, pallor, anorexia, loss of weight, slight fever, and night sweats, hemoptysis.

4. In *aortic stenosis*, there is a systolic murmur heard loudest at the base of the heart, and transmitted into the carotid arteries; the pulse is characteristic, being small and slow. In *mitral insufficiency*, there is a systolic murmur heard loudest near the apex and transmitted to the left axilla and sometimes to the angle of the left scapula; there is frequently an accentuated second pulmonic sound; the pulse shows nothing that is characteristic.

5. The renal conditions resulting from arteriosclerosis are those found in chronic interstitial nephritis. The symptoms are: Increased arterial tension, enlargement of the left ventricle and then of entire heart, accentuated second aortic sound, retinitis, choked disc, anorexia, nausea, vomiting, diarrhea, uremia, dyspnea, dry and itching skin; the urine is increased in quantity, and has a low specific gravity, albumin is either absent or present in very small quantity; a few hyaline casts may be present.

6. *Alcoholic cirrhosis of the liver.* "Obstruction of the portal circulation first causes congestion and catarrh of the stomach, hence the initial symptoms are anorexia, fetor of the breath, fullness and distress after eating, eructations, nausea, vomiting of mucus, flatulence, and constipation. For months, and even years, these phenomena may be the only evidence of the disease. As the pressure in the portal system increases, the collateral vessels enlarge, and as a result the superficial abdominal veins become prominent and hemorrhoids develop. Engorgement of the portal system also leads to ascites and swelling of the feet, to enlargement of the spleen, and not infrequently to copious hemorrhages from the stomach or bowel. The size of the liver varies; it may be increased or diminished. There is a gradual loss of flesh and strength. The skin is muddy in appearance, but conspicuous jaundice is not common and occurs only as a complication, nervous symptoms—delirium, stupor, convulsions, and coma—occasionally appear toward the end of the disease. They are probably due to the retention of poisons that the liver is unable to convert or to eliminate. The majority of cases terminate fatally in from three to five years, or in from one to two years after the compensatory circulation fails. Death results from exhaustion, hemorrhage, pulmonary edema. intercurrent disease, or toxemia."—(Stevens' *Practice of Medicine.*)

7. *Deflections of the nasal septum* may cause: Obstruction to inspiration; catarrh of the nasopharynx; hypertrophy of middle or inferior turbinated bone on the non-obstructed side; atrophy of turbinated bone on the obstructed side; interference with hearing; mouth-breathing.

8. The *leucocytes are increased* in: Inflammatory diseases, abscesses, certain infectious diseases (such as erysipelas, pneumonia, meningitis, diphtheria), lymphatic leukemia, splenomedullary leukemia.

Leucopenia is found in: Pernicious anemia, typhoid, and miliary tuberculosis.

9. *Intestinal perforation in typhoid fever:* Sometimes there is severe, sudden pain localized in the abdomen, and sometimes there is little or no pain. Marked tympanites, great weakness, collapse, anxious look, small, rapid pulse, and difficult breathing are present. The legs are apt to be drawn up, and nausea and vomiting may ensue. Hepatic and splenic dulness disappear, and leucocytosis may be present.

10. *Symptoms of myxedema:* The body becomes swollen and edematous, but does not pit on pressure; the skin is dry and rough; the hair is brittle, and tends to fall out; wrinkles are obliterated, and the face assumes a stolid expression; the muscles become flabby; movement, mental processes, and speech become slow; the temperature of the body is subnormal.

The condition is significant of lack of thyroid secretion.

11. *Wrist-drop is an important symptom* in: Paralysis of the musculo-spiral nerve due to lead poisoning or multiple neuritis.

12. *Physical signs of lobar pneumonia:* "*Inspection* reveals during the first stage deficient movement of the affected side, due to pain. The apex-beat is normal in situation, and the interspaces do not bulge. In the second stage the healthy side rises normally, the affected side lagging behind. If both lower lobes are impervious to air, the diaphragm cannot descend and the epigastrium does not project during inspiration, the breathing being conducted by the upper part of the chest (superior costal respiration). *Palpation* during the first stage shows the vocal fremitus to be more distinct than normal, especially over the diseased portions. In the second stage, the vocal fremitus is markedly exaggerated, except in those rare instances of occlusion of the bronchi by secretion. The cardiac impulse is felt in the normal position. *Percussion*—In the first stage, the percussion note is slightly impaired at times, having a hollow or tympanitic quality. In the second stage there is dullness over the affected parts, with an increased sense of resistance. Over unaffected adjoining areas the resonance is increased (Skoda's resonance). *Auscultation.*—In the first stage there is heard over the affected part a feeble vesicular murmur, associated with the true vesicular or crepitant (crackling) râle, heard at the end of inspiration only. In the second stage there is harsh, high-pitched, bronchial respiration, at times resembling a to-and-fro metallic sound, except in those rare instances in which

the bronchi are more or less filled with secretion. Bronchophony, or distinctly transmitted voice, is present and at times pectoriloquy, or distinct transmission of articulated sounds, may be heard. In the third stage, the breathing changes from bronchial to bronchovesicular and the crepitant râle (crepitatio redux) returns. As resolution proceeds, the breath sounds are associated with large and small moist and bubbling râles."—(Hughes' *Practice of Medicine.*)

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†	
Alabama*	W. H. Sanders, Montgomery	Montgomery	
Arizona*	J. W. Thomas, Phoenix	Phoenix	
Arkansas	T. J. Stout, Brinkley	Little Rock	Nov. 14
California	C. B. Pinkham, Sacramento	Los Angeles	Oct. ?
Colorado	David A. Strickler, Empire Building, Denver	Denver	Oct. 3
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	Nov. 14
Delaware	J. H. Wilson, Dover	Dover	Dec. 12
Dist. of Col'bia	E. P. Copeland, Washington	Washington	Oct. 10
Florida*	E. W. Warren, Palatka	Palatka	Dec. 5
Georgia	C. T. Nolan, Marietta	Atlanta	Oct. 10
Idaho*	Charles A. Dettman, Burke		Oct. 4
Illinois	C. S. Drake, Springfield	Chicago	
Indiana	W. T. Gott, Crawfordsville	Indianapolis	Jan. 9
Iowa	G. H. Sumner, Des Moines	Iowa City	
Kansas	H. A. Dykes, Lebanon	Lebanon	Oct. 10
Kentucky	J. N. McCormack, Bowling Green	Louisville	
Louisiana	E. L. Leckert, New Orleans	New Orleans	Nov. 30
Maine	F. W. Searle, Portland	Portland	Nov. 14
Maryland	J. McP. Scott, Hagerstown	Baltimore	Dec. 12
Massachusetts*	W. P. Bowers, State House, Boston	Boston	Sept. 12
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Lansing	Oct. 10
Minnesota	T. McDavitt, St. Paul	Minneapolis	Oct. 3
Mississippi	J. D. Gilleylen, Jackson	Jackson	Oct. 24
Missouri	J. A. B. Adcock, Jefferson City	Kansas City	Sept. 18

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

ALCOHOL—Its Influence on Mind and Body. By EDWIN E. BOWERS, M.D. Published by Edward J. Clode, New York. 207 pages. Price, $1.25 net.

INTERNATIONAL CLINICS. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles on Treatment, Medicine, Surgery, Neurology, Pediatrics, Obstetrics, Gynecology, Orthopedics, Pathology, Dermatology, Ophthalmology, Otology, Rhinology, Laryngology, Hygiene, and Other Topics of Interest to Students and Practitioners. By Leading Members of the Medical Profession Throughout the World. Published by J. B. Lippincott Company, Philadelphia and London. Volume II. Twenty-sixth Series, 1916, illustrated, 311 pages. Price, $2.00.

COLLECTED PAPERS OF THE MAYO CLINIC, Rochester, Minn. Edited by Mrs. M. H. Mellish. Published by W. B. Saunders Company, Philadelphia and London, 1916. Volume VII, 1915, 983 pages. Price, cloth, $6.00 net; half morocco, $7.50 net.

THE AFTER-TREATMENT OF OPERATIONS. A Manual for Practitioners and House Surgeons. By P. LOCKHART-MUMMERY, F. R. C. S., Eng. Published by William Wood & Company, New York. Fourth edition. 275 pages. Price, $2.25 net.

THE INTERNATIONAL MEDICAL ANNUAL. A Year Book of Treatment and Practitioners' Index. 1916. Thirty-fourth year. Published by William Wood & Company, New York. Illustrated. 735 pages. Price, $4.00 net.

PROGRESSIVE MEDICINE. A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. June 1, 1916. Edited by Hobart Amory Hare, M.D., assisted by Leighton F. Appleman, M.D. Published by Lea & Febiger, Philadelphia and New York. 482 pages. Price, $6.00 per annum. Volume II.

THIRTY-FIFTH ANNUAL REPORT OF THE STATE DEPARTMENT OF HEALTH OF NEW YORK, for the Year Ending December 31st, 1914. Published by J. B. Lyon Company, Printers, Albany, 1916. Volume II. Report of the Sanitary Engineering Division, 502 pages.

THIRTY-FIFTH ANNUAL REPORT OF THE STATE DEPARTMENT OF HEALTH OF NEW YORK, for the Year Ending December 31st, 1914. Published by J. B. Lyon Company, Printers, Albany, 1916. Volume I, 876 Pages.

GENERAL SURGERY, THE PRACTICAL MEDICINE SERIES. Comprising ten volumes on the year's progress in medicine and surgery, under the general editorial charge of CHARLES L. MIX, A.M., M.D., Professor of Physical Diagnosis in the Northwestern University Medical School. GENERAL SURGERY, by JOHN B. MURPHY, A.M., M.D., LL.D., F.R.C.S., England (Hon.) F.A.C.S. Published by the Year Book Publishers,, 327 S. La Salle St., Chicago. Volume II. Series 1916. Illustrated. 620 pages. Price, $2.00. Price of the series of the ten volumes, $10.00.

OPERATIVE MIDWIFERY. A guide to the difficulties and complication of Midwifery practice. By J. M. MUNRO KERR, M.D., C.M., Glas. Published by William Wood & Company. MDCCCCXVI. Third edition. Illustrated. 725 pages. Price, $6.00 net.

ASEPTIC SURGICAL TECHNIQUE. With especial reference to gynæcological operations together with notes on the technique employed in certain supplementary procedures. By HUNTER ROBB, M.D. Published by J. B. Lippincott Co., Philadelphia and London. Fifth edition. Revised. Illustrated. 44 text figures and 24 plates. 292 pages. Price, $2.00 net.

INFECTIONS OF THE HAND. A Guide to the Surgical Treatment of Acute and Chronic Suppurative Processes in the Fingers, Hand, and Forearm. By ALLEN B. KANAVEL, M.D., Assistant Professor of Surgery, Northwestern University Medical School, Attending Surgeon, Wesley and Cook County Hospitals, Chicago. Published by Lea & Febiger, Philadelphia and New York, 1916. 499 pages. Illustrated with 161 engravings. Third edition, thoroughly revised. Price, $3.75.

MENTALLY DEFICIENT CHILDREN. Their Treatment and Training. Fourth edition. By G. E. SHUTTLEWORTH, B.A. M.D., and W. A. POTTS, M.A., M.D. 284 pages. Illustrated. Published by P. Blakiston's Son & Co., Philadelphia, 1916. Price, $2.50 net.

SEX PROBLEMS OF MAN IN HEALTH AND DISEASE, A Popular Study in Sex Knowledge. By MOSES SCHOLTZ, M.D. 168 pages. Published by Stewart & Kidd Co., Cincinnati, 1916. Price, $1 net.

CEREBELLAR ABSCESS, ITS ETIOLOGY, PATHOLOGY, DIAGNOSIS, AND TREATMENT, Including Anatomy and Physiology of the Cerebellum. By ISIDORE FRIESNER, M.D., and ALFRED BRAUN, M.D., F.A.C.S. 180 pages. Illustrated. Published by Paul B. Hoeber, New York, 1916. Price, $2.50.

CLINICAL DISORDERS OF THE HEART BEAT. A Handbook for Practitioners and Students. Third edition. By THOMAS LEWIS, M.D., D.Sc., F.R.C.P. 116 pages. Published by Paul B. Hoeber, New York. Price, $2.

ULTRA-VIOLET LIGHT by Means of the Alpine Sun Lamp; Treatment and Indications. By HUGO BACH, M.D., Bad Elster, Saxony, Germany. Authorized Translation from the German. 114 pages. Published by Paul B. Hoeber, New York, 1916. Price, $1.

MODERN MEDICINE AND SOME MODERN REMEDIES. Practical Notes for the General Practitioner. By THOMAS BODLEY SCOTT, with a Preface by Sir LAUDER BRUNTON, Bart., F.R.S. 152 pages. Published by Paul B. Hoeber, New York, 1916. Price, $1.50.

DOGMATIC PHYSIOLOGY.

BY J. ALLEN GILBERT, PH.D., M.D.,

PORTLAND, ORE.

THE average physician has but little interest in psychology. He knows comparatively little in regard to it and gives it comparatively little importance among the various branches of science. In fact he is loath to accord it any existence at all as a separate science and classifies it for convenience as a branch of physiology. For him mind is but a product of brain, sensation a modification of the brain cell, consciousness a mere effervescence from nerve matter and thought in general a side issue having reference only to the brain that gave it birth. The ultimate fact is functioning matter. Psychic data are but shadows of the real thing. The atom is his God and force his mainspring. With these two fundamental realities he spins off with infinite satisfaction the whole series of physical and psychological phenomena, always withholding from psychology a standing in any way equivalent to that of the objective sciences. He rides over contradictions in his statements with a complacency which is admirable for its audacity. Materialistic in his tenets he is nevertheless ultra-idealistic in his actions and in his demands upon the actions of others. Though he may not adhere to any definite rule of action he always demands it of the other man. In his daily life he belies the tenets which he defends so vigorously on theoretical grounds. Psychological inquiry is reserved as a sort of mental gymnasium, but the real work of life is to be found in the more tangible phenomena of physics and chemistry, which he looks upon as stable and abiding. The laws of perception do not bother or worry him in that he knows but little of them.

In a sense one feels prompted to apologize for bringing up anew a subject which has been so thoroughly discussed in years gone by, and yet after years of work in a psychological atmosphere it makes one shudder to observe the boldness with which physiology asserts herself in medical circles. Has psychology no relation to metabolism and general therapeutics? Is the physical organism a mechanism with no kinship to the higher emotional aspects of man's nature? Is there nothing of man but the chemical process known as physiology? Whatever answer we may give to such questions it is evident in medical circles that physiology has usurped the throne and hands down its dicta with a positiveness which is far less critical in its fundamental tenets than the old-time dogmatic theology.

Not all physicians boycott the psychic. However, the average physician's training is confined to dealings with the material side of man and in the absence of supplementary interest in psychology he sees only the physical and rules out as irrelevant all phenomena that can not be subjected to his pet atomic theory. He begins his studies in the dissecting room. Here he finds what are to him fundamental facts in the shape of nerve, muscle, and bone. They are what is left of a former physiological mechanism worn out and yet sufficiently intact to suggest the *modus operandi ante mortem*. He begins where psychology leaves off, and failing to find the higher emotions, he naturally assumes their effervescent nature and subsequently wastes but little time upon them. Working backwards his whole aim is to learn how the machine ran down. Physiological processes are no longer apparent except in the foul odor which fills the room. The process of decay attracts his attention, but he little realizes that here the same chemical forces are at work as those he later encounters in the test tube or in the blood coursing through the arteries of a vivified organism. Later study of the physiological processes which account for the metabolism of the body gradually leads him up to and prepares him for the climax of organic chemistry, viz., the process of reproduction. Clinging to the criterion of visible change for his recognition of reality the higher emotions escape his attention because of the all-absorbing attractiveness of the changes he can trace and put his finger upon. Like the child who quickly differentiates the moving light from the confusion of stimuli which fill his limited mental horizon he fastens his faith upon *that which moves*. Very quickly his system of thought is hinged upon the motion of things and nothing so thoroughly enlists his admiration as that form of motion which is manifest in reflex or automatic processes as if in them were to be found a spontaneity of activity most nearly akin to motion *as such*. He is finally satisfied with explaining all reality upon the basis of the atom in motion.

On the accouchement bed, later in his experience, he delivers the new-born child as a mere bundle of reflexes into which he at times literally breathes the breath of life. It never becomes more to him than a bundle of reflexes which automatically develops a machine of infinite intricacy, wears out, and suffers dissolution. He spends his last futile efforts upon the post-mortem investigation, trying to discover why the machine ran down and with the tabulation of a pathological finding upon the death certificate dismisses the whole affair from his mind, with possibly no acquaintance whatever with the true man whose inner life was a sealed chapter to him.

Psychological phenomena persistently intrude themselves upon his attention and in the majority of instances they are with equal persistence pushed aside as irrelevant. They merely serve to help him locate the difficulty with the machinery. Of their

true significance he has but little conception. Medical terms are not made to fit them. They destroy the harmony of his theories. He identifies them with hysteria, which, to the average physician, is a sort of psychological dumping ground for all phenomena which disorder his materialistic postulates. They are uncanny, mystical and superfluous so far as his interpretation of the mechanism of the universe is concerned. Except for an occasional plea of hysteria or insanity he has no need of them. They are in his way. With an authoritative wave of the hand he dismisses them as mere products of the brain and proceeds with his physiological investigations.

This attitude toward psychic phenomena continually compels him to confront contradictions and difficulties which he is unable to explain. Physiology answers his queries with a dogmatism characteristic of the so-called objective sciences. Without investigation the objective thing with its corresponding function is posited and accepted as the fundamental fact, little realizing the difficulties to be encountered in accounting for the intangible facts of consciousness which are as obstinate as any that science has to deal with. Whether he will or not he must face certain conceptions which daily experiences thrust upon him.

In the following paragraphs it is desired to discuss briefly a few of the problems which continually drive the materialistic physician into contradictions and to which physiology has no answer except by way of a dogmatism without ground or explanation.

Is Mind an Entity?—The answer that one gets to this question in medical circles is often amusing. Physiology answers with a derisive grin. Loyalty to what she conceives to be scientific methods urges the necessity of subjecting all reality to the various methods at the disposal of the so-called objective sciences. One does not advance very far, however, on such a postulate until he finds himself in a hopeless tangle of contradictions. But contradictions seem to have no effect upon the mental equilibrium of those materialistically inclined. The usual mode of escape is simply to deny any existence to mind as such, referring all phenomena to a physiological process or to a mechanical result of atoms in motion. The explanation contains more difficulties than the thing to be explained.

In the light of modern progress it would be folly to emphasize the value of laboratory research because it is universally recognized. Everybody realizes its importance, but to hope that all phenomena may eventually be subjected to the methods of physics is to reverse utterly the true order of things. Physiology and biology fail altogether to explain the difficulties which a physician faces daily: and when one forces psychology into the realm of physics it is inconsistent and unscientific to demand that she shall assert and defend herself in terms of a science entirely foreign to her true nature in their fundamental tenets. Men have always demanded proof that they exist, whereas the fundamental principle of psychology—in fact of all thought—must be accepted without proof or question. To question its existence is in fact one of the best proofs of the incorrectness of the tenet which affirms its nonexistence. Absolute doubt leaves no ground for proof.

He who attempts either to define or to explain himself will continually find himself falling back upon the unexplained in his explanation. He must accept himself to start with. This is the only point upon which psychology dogmatizes, if dogmatism it be to accept your own existence without question. The physiologist by way of contrast posits the universe in space and then proceeds to try to get himself out of it, little realizing that through perception he has been instrumental in delineating external stimuli into an objective spread-out world capable of interpretation in terms of motion. He balks at the conception of a continuum of self as a basis for experience simply because, so far as he can observe, there seem to be breaks in consciousness. For him, that only persists which gives continuous objective evidence of its existence. He must be able to check it up and keep account of it. So far as personal experience is concerned, it matters but little whether there are breaks in the continuity (as the physicist views that term) so long as the experiences of the past are linked to or unified with those of the present. Experience knows no gaps. Because there are so-called gaps in consciousness is no argument against the continuity or identity of self. He who picks up his past and identifies it as his experience is but realizing his own identity. He identifies himself, as it were, by the persistence of a given perception group. He thus becomes a unit in the great social scheme upon which civilization itself is dependent. Other men learn to know him as an individual—not merely as an individual animal organism with certain anatomical and physiological attributes or functions, but as a subject taking his position in a certain social scheme where morals, esthetics, ideals, and relation in general hold sway. But what will physiology do with an ideal? How can it classify an ambition? How will it evolve a conscience or a noble determination? Where is the beauty of a landscape except in that unity of consciousness which asserts its own identity? Let a man lose that identity of self and he is immediately and justly dealt with as a mere physiological mechanism until such time as he can "give an account of himself" again. When he does he again becomes a vital force in society politic. We may trace out the infinite complexity of nerve ramifications as an explanation of psychic content and yet the personal equation slaps back at us with a resiliency which upsets all our calculations. We find ourselves face to face with a psychological resistance which refuses to be explained away by any lengthy disquisitions on "matter in motion." The self-assertiveness of the individual is a phenomenon which fails to find its *raison d'être* in a concatenation of atoms and molecules, while sociologically the psychological unit is an indispensable entity. Out of that unity of self-consciousness springs the long list of ideals upon which man builds his social structure. From that unitary entity known as self we build all our more general conceptions of the universe which lead us back in our thought to a unitary basis for all reality. While such mental gymnastics in search of a Kantian "Ding an sich" may not prove of practical value, yet it verifies the persisting entity upon which all such speculations depend. All men reason backward to some such all-embracing entity. The religious enthusiast calls it God and endows it with all his anthropomorphic emotions; philosophy, perhaps more staid in voicing its creed, resorts to the impersonal by choice of a more general abstract term such as the "absolute"; science with her breadth of differentiating classification calls it "nature"; physics sees in it pure "force," while psychology interprets in terms of her own

vernacular and calls it "mind." It makes but little difference what you call it. All such names lead to a common source, viz.: the self-conscious entity which we know ourselves to be. It is the unit to which all experience has reference and on which all scientific knowledge rests. Physiology herself, as a science, is impossible without it.

The Necessity for Unity.—Science is but a classification of accumulated data and every science requires its fundamental unit. If it has none it creates one upon a hypothetical basis. It must have one. In most cases it is a borrowed conception. The only real unit is to be found in psychology and from the unity of consciousness other sciences build up or posit a unit purely hypothetical in nature. The physical sciences have struggled for years to obtain an absolute unit upon which to base their deductions and inductions. The only thing they have is a manufactured product based upon the unity of consciousness. Instead of reducing the multiplicity of separate elements to be dealt with in physiology the laboratory has only multiplied their number. The farther chemistry goes the more so-called units she is compelled to add to her list of elements. The fact is that objective science has no real unit. The atom of physics is purely and simply a transference of self into a foreign science. The same is true of the unit of mathematics. The mere process of counting begins with the positing of self as the unit from which we start. Addition and subtraction are but a duplication of the unity we conceive and know ourself to be. Not only do we duplicate our unity in things but all relations of things can have meaning only as they are referred to this unit for consideration, comparison and classification. Any individual object is one only as we give it a separate existence—a selfhood as it were—analogous to our own. Unless we do this the external world has no unit. Division and subdivision finally drive us to the indivisible and thus by a leap into the dark we posit the indivisible atom which is in reality only a hypothetical unit based by analogy on the unity of self. Ignoring all perception the physiologist posits the atom as the real abiding unit, and through interaction of atoms he evolves the physical organism and consciousness with all its complexity. The unity of consciousness from which the atom as a basic unit got its birth is relegated to an unimportant position as a mere product of the interaction of atoms. Nothing could be more completely reversed than such a conception. The reality of self is sacrificed to a mere abstraction which is based upon the very reality of the self whose existence is denied. As investigation proceeded the atom became insufficient to explain all phenomena and the daring scientist took another leap into the dark and fastened his faith upon the ion of which we are told there are thousands in one atom. It would have been safer to posit millions of them instead of thousands. How long will it be before the imagination becomes dissatisfied with the ion and makes another leap into the dark? No unit is divisible. Back again we go to the I that is always I—the only real unitary entity of experience.

Science is dependent upon a unit as the basis of classification and is impossible and inconceivable except as it refers to a unitary basis which makes classification possible. Classification is not explanation, but it does at least force one back to an admission of the underlying unity of personality which makes classification possible. So, eventually every ultra-scientific medico, it matters not how materialistic he may be, must pay his respects to a psychological principle and at least admit the validity and reality of his own unitary perceptive consciousness.

The Atom.—This mighty mite has dominated the medical mind with a relentless hand. It is the physician's Frankenstein creation. Built from his own deductions it has turned upon him and dominates all his researches. He has built it up and endowed it with his own perceptions till at the present time it well-nigh controls medical postulates. Having posited the atom as the source of the objective world and endowed it with all the possibilities of physiological processes he finds no difficulties in building up a harmonious universe explicable in terms of physiology or atoms in motion. Nothing could be more contradictory. In the first place the atom is only hypothetical and in the second place motion can have no significance except as it refers to some unitary entity capable of throwing things in relation one to the other. Relation means nothing when divested of its conscious content. Any quality or any phenomenon the physiologist finds hard to harmonize in the world about him he ascribes to the inherent nature of the atom itself. Thus all difficulties are swept away by merely assuming their solution in the inherent nature of the atom. Naturally one is able to draw out anything he puts in. More and more inexplicable phenomena have been packed into this indivisible and yet elastic hypothetical unit until it has finally burst, releasing thousands of ions which now stand at the horizon of man's imagination. Such a process gives breathing space to the imagination for a time, but one fails to see wherein any advantage has been gained by shifting the finality one step farther back. To back-water is always embarrassing and since the atom is but a hypothetical basis of explanation it would seem advisable to fortify ourselves against any possibility of attack by positing an ultimate unit sufficiently flexible or absorptive to embrace any possibility that might arise. The atom is but the outward demonstration of the effort of the human mind to settle upon some unit as a starting point in explanation. Physics has no other way of reaching unity except by dividing and redividing till a thing (?) is reached which is so small that you can not make two out of it—a purely spatial conception.

Explanation.—Explanation is, strictly speaking, only relative. It begins and ends in the unexplained. Certain axioms of thought have to be accepted without explanation and the final explication of any phenomenon has within it the original inexplicable postulate. We accept many things as self-evident merely because they are of daily occurrence, but when we stop to explain even the simplest of them we find it wholly as difficult as to explain the universe itself. Physicians hold up their hands in horror at anything like dogmatism and yet no class of scientists is more dogmatic than they. They are sticklers for explanation and yet thrust upon you certain postulates which you are expected to accept. To question their validity brands you as unscientific. What can be more dogmatic than the positing of an atom as the basis of all physics and physiology when all admit that experience is the source of all scientific knowledge. Physiology merely dogmatizes on the fundamentals and expects us to admire her as she juggles the various facts of experience in an attempt at explanation. No one ever saw an atom or handled one. Metaphysics is decried by the physiologist as sophistry

and yet what could be more metaphysical than this fundamental atom? The real unit of thought which makes theory possible is ignored and reality is bestowed upon a thing that is theoretical and metaphysical through and through. Physiological changes are undoubtedly chemical in nature and where processes are seen to work out to a definite end or desired result we immediately recognize a systematic organization of forces and tend to personify the process, as it were, and forget the real underlying fact of experience. After all, psychology, with all her self-confidence, is but a process. The chemical and mechanical changes which take place in a physical organism represent the true activity and are called physiology when worked up into a system of chemical changes to a certain end. Hence physiology as a science is teleological in nature and is scarcely fitted to dogmatize upon the results of chemical changes or upon the nature of the elemental agencies at work in the process.

Scientific explanation is but accurate classification. Certain qualities are grouped according to their similarity. When we chance upon an element simple in nature and at the same time persistent in its uniformity of action we say we have an original element. On the basis of these we then proceed to *"explain."* Such explanation can be nothing but a narration of perceptions regarding the activity of so-called things and physiology's only method of noting activity is in terms of motion. Hence, by a reverse process, physiology argues that all phenomena are but matter in motion—a conception thoroughly saturated with contradictions.

One *must* dogmatize on the knowledge of self. Every theory of knowledge has in it that element of dogmatism which asserts knowledge of self without explanation or question. Through perception a so-called knowledge of things other than self is attained. Not that the perceptive process is a thing tacked onto the mind as such, but in the knowledge of self mind and things fuse with an intimacy which defies ultimate analysis. To the average physician such a conception has no meaning. By a biochemical activity of the cortical centers of the brain, mind is evolved by him; and even after it is thus produced it is denied any reality other than a non-abiding effervescence from brain commotion. Dogmatism? Not only dogmatism but a complete reversal of the path along which science has advanced. The very brain itself is dependent upon perception for its proper position or classification in the scientific world. As a thing belonging to the so-called objective world it must submit to certain categories of mind before it can assume its position as head of a nervous system in a general classification of histological structures. No—*explanation must begin with the grounds of explanation.* Knowledge is axiomatic.

Relation of Mind and Body.—Nowhere are the physiologist's difficulties more pronounced than in his attempts to explain the relation of mind and body. In one breath he denies that mind is an entity at all and in the next speaks of the effect of mind on body. Physiology always offers something tangible, but in mind the physiologist finds nothing to put his finger upon and hence he gives it no reality.

On principles of physics and physiology by what right does he call mind a product, for a product must still have the physical properties or qualities of matter and contain within it the constituent elements which produced it. At times to extricate themselves from such a dilemma they assert bodlly that *"mind is the cortex,"* regardless of the contradictions involved. After the smoke of such an argument has cleared away one's self always comes back with a vividness all the more striking because of the acuteness of self-consciousness engendered b the psychic resistance involved in such a struggle. One becomes all the more convinced of one's own reality and in the same relative degree suspects that possibly the difficulty lies in one's own conception of the nature of body rather than in the nature of mind. Physiology catches herself dogmatizing in regard to things of which she knows nothing and to extricate herself always falls back inconsistently on experience which is essentially psychological in nature.

Things are not the dead inert masses we are sometimes prone to consider them. They have an activity of their own and an individuality revealed by their own spontaneous activity. Under existing conditions there is an interdependence between mind and things which defies analysis. Neither exists without the other—in fact both dip back into the same throbbing sea of activity which we call reality. Take from so-called things all the elements having a conscious content and there is nothing left but an abstraction. The fact that external stimuli are built up into things by a conscious process does not make them any less real but only adds to them the qualities and attributes which make them spatial objects to be dealt with in terms of physics. This conception does not reduce things to subjective realities but merely does away with all antagonism between so-called mind and matter which in fact blend with an intimacy which defies analysis. To explain the relation of mind and body is then the same problem as to explain our relation to each other or to explain the relation of things one to the other. Neither is the product of the other. Thus it is folly to waste time denying existence to either one or the other. Both must be accepted, but the nature of the two for scientific classification must depend upon the grounds of knowledge of the two. Matter, as physics depicts it, is devoid of any characteristics which make knowledge possible, whereas psychology presents a basis of knowledge which is accepted by all men whether civilized or savage. No two men will agree as to the nature of matter but all men agree to the fundamental knowledge of self, which is the *sine qua non* of all scientific thought. Thus all men find common ground in the acceptance of the facts of consciousness. To prove that that which is known as the external world also reacts in terms of consciousness would be difficult, if not impossible, but it leaves us at least with the conviction that those activities known as things in some way carry on an existence comparable to our own.

Structure and Function.—"Structure" and "function" are terms with but little ultimate difference in meaning and are used for convenience to define different aspects of the same thing. In one sense a discussion of such terms is the same old query as to "which is first, the hen or the egg?" and yet physicians dwell upon structure as the essential element while function, as they see it, is but a play of forces secondary to and dependent upon the underlying anatomical basis called structure. It is readily admitted that if you remove structure (assuming that to be possible) there would be no function, but it is equally true that if you take function from structure (assuming that also to be possible—which

it is not) there is no structure left. Both suppositions are impossible. Any entity without its active principle is an abstraction—such suppositions are not only ridiculous but impossible. Structure and function are literally synonymous. To function is the very essence of existence and structure is but the visible evidence of function rather than the basis of it.

Within the kidney of the living animal are taking place certain chemical and mechanical changes which result in the formation of urine. The kidney which has ceased to secrete urine is nevertheless functioning with exactly the same chemical stringency as before cessation of the flow of urine. The tender vine rotting on the rubbish heap, torn from its roots, is as active and cogent as it was with all the possibilities of a fruitful harvest ahead of it. Its activities have simply changed direction, due to a change in surrounding circumstances. To speak of living and dead material is but figurative. The changes going on in a mammary gland have their exact equivalent in the granite crumbling on the hillside. The gland literally becomes milk. By a truly chemical process there is a changing combination of the elements of the cell by which it breaks down and the resultant of the chemical forces at play is milk. The gland has literally given up itself to make milk. Here, then, the processes of secretion and decomposition become identical. The only difference lies in the psychological interpretation. Teleology has crept in. It is as truly the function of iron to secrete rust as it is the function of the mammary gland to secrete milk or of the kidney to secrete urine. Is an oxygen atom dead in water and alive in blood, inert in iron and active in the plant? The activity of iron in forming rust is as spontaneous as that of the mammary gland in secreting milk. The only difference lies in the psychology of the affair. To ascribe life to one form of reality and deny it to another is but to change words without a distinction. Actual transformation of the mineral into the vegetable and animal goes on daily before our eyes and vice versa. A boundary line is absolutely impossible. Chemistry knows no "dead." To place a structural atom back of the atomical function which we experience is but a metaphysical substructure for function to rest upon, whereas function was the reality with which we began and which alone we know. Here is where the dogmatism of physiology becomes most manifest. Structure is postulated and function is tacked onto it.

The Possibility of Psychotherapy.—Here the difficulties of physiology become even more manifest. Our answer as to whether psychotherapy is possible must depend entirely upon what significance we grant to psychic processes. If mind is to be looked upon as matter, or as matter in motion, or as a product of matter, then the possibility of interaction is not denied by any one, for all admit the action of one particle of matter upon another. If we find it impossible to identify mind and body, the only alternative left to him who clings to the materialistic hypothesis is to look upon consciousness and all psychic phenomena as a sort of hybrid effervescence from brain tissue incapable of organizing itself sufficiently to react upon the brain which gave it birth. There is still another escape left to the materialist and he frequently avails himself of it, viz., to deny the existence of consciousness *in toto*, which is simply intellectual suicide. This would preclude the possibility of any discussion whatever.

To assume the possibility of psychotherapy at all forces upon us the admission that mind must have or be an entity in some sense comparable to the reality we call matter, else action and reaction would be impossible. It is immaterial what names we apply to the various aspects of reality so long as we admit the reality of anything which we introduce into our scheme of action and reaction. If we hold that mind is but a product of matter, we are forced either to the conclusion that mind as such a product has no activity of its own and hence can not affect matter; or else we must admit that the material product (mind) is a handiwork of another part of matter. This, however, is impossible according to physics. If consciousness is a function of matter, the product or result of that function according to physical laws must be a physical product; which is again contrary to the ultra-materialistic idea of consciousness. If mind is matter then mind should, yes must be an object of perception, for matter is by nature an object of experience. Hence one part of matter perceives another part of matter which again is contrary to physics, though in reality it is not far from the truth.

One could cite an indefinite number of contradictions in the physiological postulate, but all are based upon the fundamental error in refusing to admit our own existence as the starting point of all scientific attainment. Matter must be interpreted in terms of consciousness and consciousness of self must be accepted without question and without explanation. Accepting consciousness as our starting point, all reality must be interpreted as in some sense conforming to the rules governing conscious life; and this postulate is easy of acceptance when we vivify all nature into one huge acting and interacting maelstrom of reality.

From the standpoint of physiology the product of cerebration would still be a physical entity, but no physiologist looks upon the product of cerebration as still physical or as even having the qualities of matter. He assumes the brain as ultimate material abiding fact and consciousness is looked upon as secondary, non-material, and evanescent with no abiding essence to give it the right of existence as such. He refuses to give it any further significance or causative efficacy though he repeatedly escapes his own inability to explain the facts which confront him by ascribing them to the effects of mind on body. The fundamental error lies in the assumption of a structure preceding function, whereas structure and function are synonymous from the standpoint of explanation. Action and interaction are identical except in the psychological or teleological interpretation we put upon them. In the same way mind and matter are but terms to designate certain activities in certain conditions and their relation only calls for explanation in determining the nature of the phenomena encountered in experience. The kernel of the dispute lies in the nature of so-called matter rather than in the nature of mind which every man knows by direct experience. The average physician assumes accurate, definite knowledge of the objective world and feels called upon to account for the existence of consciousness after accepting matter as an assumed fact, whereas consciousness is the basis of explanation and objective things call for explanation.

This tenet does not deny reality to objective things nor does it preclude the possibility of faithful adherence to scientific methods. It is only an

appeal for the recognition and classification of any fact whatever its nature may be, and if there is any fact known to science it is the primal fact of consciousness. Either that existence of a mental process must be denied *in toto* or else we must admit the mutual interaction of so-called "matter" and so-called "mind." A discussion of the nature of mind does not come under the present discussion.

Sanity and Insanity.—Pray tell, what can sanity or insanity mean in the light of physiology or physics? Nature slips no cogs. She knows no freaks. A freak is a freak only from the standpoint of classification, and classification is psychological and not physiological. Exceptions arise from faulty or inadequate classification. The very essence of sanity is self-consistency and if all phenomena, mind included, are but a mechanical outcome of atoms in motion, then consistency *must* follow. No mere mechanism is crazy. As the astronomer peers into the sky and discovers the comet with its unusual action, he does not presume to assert that it is crazy merely because he can not properly classify it or explain its actions. The general balance of the heavenly forces compels him to accept a universal concert of action and the comet only emphasizes his limitations in knowledge. On the same grounds physiology notes the chemical changes and, in consistency with the laws it observes, every datum should merely be accepted and classified. Judged by the laws of physiology no act could be called insane. As an act it merely calls for classification. Its consistency with what goes on about it is a fact to be accepted on the basis of the fixed postulates of physiology. Once having dogmatized on the mechanical nature of the process underlying all phenomena, physiology surrenders her right to judge any act as regards its fitness, adaptability, or teleological significance. The fact carries its own qualifications with it, viz., its existence. It is a unit in a mechanical process, the chain of which would be broken and meaningless without it.

Insanity carries more with it than the mere fact that the anomalous has presented itself. There is in it the element of *consistency with self*. Any act must be judged sane or insane not with reference to the community or general laws governing the actions of men, but with reference to the man himself. Any act which takes its place in a series of logical and self-consistent acts must be looked upon as sane. This necessarily infers a unitary basis or ground of action, and a diagnosis of insanity assumes the entity and reality of mind as a basis for consistency. A disconnected isolated fact can neither be sane nor insane. It must have reference to a unitary continuum of consciousness. What, I repeat, can insanity mean in the light of mere cerebration? To adjudge an act insane on grounds of physiology merely convicts us of inadequate classification. Popular methods adjudge a man insane who does not act as other men do, whereas the true diagnosis of insanity rests, not upon a comparison with the general consensus of opinion, but upon the consistency or inconsistency of one's own acts with reference to each other. Man has within himself his own conviction of insanity or the means of defending his sanity in the absence or presence of self-consistency. One thing would seem self-evident, viz., sanity, to mean anything at all, must refer to mind and not to body. It must be diagnosed by means of the psychic manifestations of the subject. Mind has no histology and no anatomy and therefore no pathology as that term is generally used. That insanity has correlated with it a pathological nervous condition probably no one will deny. Every psychic act has its counterpart in the nervous system. However, to mistake a morbid anatomy or an abnormal physiological process for insanity is to confound consciousness with nervous activity and a neuron with sensation. A diseased brain is not a crazy idea, nor an insane man. At present but little is known of the morbid brain anatomy accompanying insanity, and at best it is known post mortem; but should even the most astounding morbid anatomy be present we must still appeal not to physiological processes but to the individual before pronouncing insanity or sanity. Could we know thoroughly the pathology and histology of the brain we could with certainty describe the mental condition of the patient and yet for a diagnosis of sanity or insanity an appeal must be made to the man. The diagnosis of sanity or insanity must rest upon the psychological examination of the man in question.

Ethics.—Every physician has his system of ethics. He may not be willing to live by it himself but he is sure to demand a certain rule of life from other men. It is difficult, however, to find any place for ethics in a system of philosophy where the entity of mind is denied and where all phenomena are but chemical change. This, however, is another of the physiologist's contradictions which apparently does not affect his devotion to his pet philosophy. Theoretically he makes ethics impossible but in practice his theoretical speculations are submerged beneath a stringent demand for what *ought* to be. In his calculations and deductions of laws psychic life has been looked upon as a by-product and hence is not incorporated in the laws he has deduced. If a law of universal application is to be established, then the fact that men *ought* to do so and so must have equal force with the fact that men *do* do so and so.

One hesitates to break in on the apparent harmony of the forces of nature by the expression of a wish that anything might be otherwise than it is, to say nothing of suggesting that certain things *ought* to have been different from what they are. The accuracy with which sets of experiments work out to a definite end can not fail to attract the attention of even the most ignorant observer. We notice the systematic consistency of the activities going on before us. Soon we find ourselves deducing a series of laws expressing that harmony of concerted action, but in our admiration for the accuracy of the workings of nature we forget that we have deduced the laws and, overawed by the universal application of the laws we have deduced, we reverse the true order of things and come to look upon these laws as governing the activity of things, whereas they merely express activity and never govern it in any sense. The act is the thing in question, and the law is but a convenient formula by which we keep track of the activity of things. Physiology as such knows nothing of laws. The chemist may go into ecstacy as he watches the transformation of substances one into another and yet the different elements entering into the combinations are but acting their individual parts subject to surrounding conditions. That an oxygen atom should respond in different ways under different stimuli from without is quite natural and yet its individual action is always that peculiar to an oxygen atom if such a statement may not seem tautological and ridicu-

lous. Any variation in what previously seemed to be unwavering persistent consistency of activity merely calls for readjustment of laws to fit the new fact or act if such it proves to be.

Hence human conduct introduces an uncertainty not because we have entered a realm whose phenomena are lawless but because our present laws are too narrow to include it. This uncertainty is due to the intrusion of an element omitted in our formulation of laws and unknown in the physical realm, viz., the personal equation. It cannot be counted upon with any degree of accuracy. While the activity of things, if analyzed thoroughly, is manifestly spontaneous in character and in its essentials does not differ from that sort of activity known as human conduct, yet in the latter conception we find a conception not to be found in the realm of physiology. It is the principle "I ought—you ought." It is incompatible with the atmosphere of the physiological laboratory. Misconduct is never considered as a possibility in the crucible or test tube. If human conduct is but the result of the interaction of atoms of the brain, why do we insist upon misconduct within the cerebral mass boiling and bubbling within the cranial crucible? No one rests satisfied with the fact that a man has done so and so. He is praised or blamed. He did what he "ought" to have done, or he "ought" not to have done what he did. No one seems willing to sit by and wait to see what a man will do. He is exhorted to do this or not to do that in accordance with the principle of "ought."

If man admits that moral obligation is a fact and not a fallacy, then our laws must be so revised as to admit this disturbing element or else the conception of human conduct and the principle of "ought" must be reduced to terms in harmony with the facts already included within the law. Either human conduct must be reduced to a physiological process stateable in terms of the atomic theory or else the action of things must be looked upon as in some way in harmony with the acts we classify as human conduct and to which we attach praise or blame. Either human conduct, courts, law, justice and rights in general are a farce or things must be given an interpretation which is broader than the present physical view will permit. The difficulty lies in a faulty conception of things. Men perceive the *relation* of things, and conduct as such is based upon this characteristic. Individual initiative is a characteristic of all activity whether it be in a post or in a man, and the only thing which differentiates human conduct is the power to see things in their relation one to another and evolve from their relation a rule of action.

Nowhere is the conflict of theories more troublesome and at the same time more manifest than in the medical mind. To the great majority of physicians the mind is a product of brain and sensation, is but a modification of cortical centers, and yet no class of men is so firm in its demands for a professional ethics, even though they may not adhere to any such code of laws. The Code of Ethics issued by the American Medical Association is their court of appeal, and no document could be more thoroughly saturated with the conception of "ought" and "ought not" than this guide to the physician's conduct. Are these precepts advising the cortex what to do? No class of men guards their professional rights with more jealous care than do these very adherents to the automatism of psychic action. In one breath they will refer all moral action to changes in brain substance, and in the next complain of the "injustice" or rascality of some fellow physician. They tell us that a certain member of the medical fraternity "ought" to be expelled from full fellowship with the elect because he did what he "ought" not to have done. To be sure, if there is no such thing as rights or justice, then the man of straw is easily knocked down; but here again no class of men is more insistent on its rights than these same advocates of the absolute dependence of consciousness on modifications of brain tissue. It is useless to waste time trying to prove that personal rights are to be admitted. Physicians not only admit it but are persistent and at times bitterly insistent upon the maintenance of their professional rights, dignity, and honor. They deem themselves consistent in it also. But, what can be meant by rights, dignity, and honor, in terms of cerebration or physiological metabolism? By what corollary to the general law of equality of the physical elements does a brain cell don the garb of selective rights and honor and pose as superior to any other cell within the body? What can be meant by development, better, higher, lower, inferior, superior, et cetera, in the realm of physiology? Such terms refer to an "ideal" which can scarcely be identified with the cortex. The ideal is based upon principle and there is no place for principle in the atomic theory. The law of tooth and claw is universal except where the ideal leaves its imprint and duty holds sway.

Either we must admit that our present physical laws are too narrow to include all data or else we must hold that all psychic life is a phantasmagorical farce made up of delusions, illusions, and hallucinations. The latter conclusion gives relaxation and peace of mind for a time, but at once there looms up before us out of the universal farce at least one fact that the farce we are enacting is real, and then the whole mental wrestle begins over again. The delusion and hallucination at least demand some consideration as entitled to reality. It has merely been an attempt to argue ourselves out of existence. Nor will we be satisfied with imaginings, phantasms, and farces. If all is farce, the consciousness of that farce still stands out as a surviving fact to belie our assumption that all is farce.

What is the elaborate Code of Ethics issued by the American Medical Association as a guide to all its members? Is it a code of predictions as to what the cortex is going to do? Is it even a list of things the cortex "ought" to do? Is it an attempt to invade the nervous system with the principle of duty? Or is it an appeal to a self-conscious personality, not only capable of initiating activity but of guarding and granting personal rights based upon the "ideal"? One thing is certain, the Code of Ethics as issued by the American Medical Association is not a dissertation on physics or physiology. It is an appeal not to the cortex but to the man.

However vigorously physicians may attack the entity of mind and the reality of morals, they seldom if ever act out their own speculations. There is a standard of morals among deterministic physicians just as cogent and binding as among any other classes of men. Though we may by mental gymnastics rob ourselves of personal rights, yet when the mental tension required in the process relaxes, our own conviction of obligation to an ideal slaps back at us with a vividness which leaves no

doubt as to its reality. Our joys and our sorrows face us with a stubbornness born of action. We quit our cogitations and proceed as before, sacrificing our rights here and demanding them there, censuring to the right and praising to the left with an inward conviction that certain things "ought" and others "ought not" to be.

The Code of Ethics then is an embodiment of the principle of rights. It is an ensemble of principles. Ideals are held up, self-respect is urged, others must be considered and selfsacrificed to their welfare. Strange reactions these to emerge from a physiological laboratory! Men must learn to be men. He who lacks *self*-respect can not be reached by a code of ethics and it is useless to enact laws unless the general *esprit-de-corps* of the profession is able to find itself reflected in them. Hence, the prerequisite of ethics would be self, not illusory, imaginary, and farcical, but real and abiding. What can physiology do with a code of ethics? Rules and men must both embody principle, and physiology as such has neither man nor principle. In order that we may respect others and their rights we must realize a self-respect which makes us subservient to principle. *i. e.* to the ideal, and ideals have reference only to personality.

SOME RECENT MEDICAL OBSERVATIONS IN THE EUROPEAN WAR ZONE.

By J. A. NYDEGGER, M.D.,

SURGEON, UNITED STATES PUBLIC HEALTH SERVICE.

After a sojourn and travel of some months' duration in the area of European war activities one should not be lacking in some impressions. A few of these impressions—confined to the field of medicine, I will endeavor to recite briefly. Reaching England May the first, and armed with letters of introduction to the heads of various European Red Cross Associations, no difficulty and but little delay was experienced in obtaining invitations to visit such military hospitals and similar institutions as was desired, although the great number of these available made it quite impossible always to select the most interesting ones. This early experience, coupled with the fact that during the greater part of the time I was busily engaged in the pursuit of other professional investigations, made it necessary to select certain types of hospitals for study, if one wished to see a variety of cases, to note the methods of treatment, and view the classes of hospital buildings and their equipment. First-aid and Field hospitals I did not have the opportunity of inspecting, but receiving hospitals, distributing hospitals, general, convalescent, and special hospitals were made freely accessible in the countries of England, Ireland, Scotland and France.

The first and perhaps most striking impressions one had, on visiting the wards of one of the large general hospitals, was the preponderatingly large number of wounded being cared for as compared to the number seen suffering solely from diseases strictly medical in nature.

Thus, in some of the hospitals visited fully 90 per cent. of all officers and men were being treated for disabilities of a surgical nature. Judging from the extent of my observations in this respect, as also from the numerous conversations had with medical officers, one would be justified in placing the general average of the wounded admitted to hospitals at 90 per cent. or above, and the medical cases at 10 per cent. or less. This low admission average of medical cases bears witness in the highest degree to the efficiency of the army sanitarians, in maintaining the soldiers' environment, whether in field, barracks, or trenches, in a high sanitary condition, and thereby maintaining the incidence of communicable diseases at the lowest possible figure. In fact, this is one of the marvels of this great war, where we realize for almost the first time in history that medical science has outwitted disease, that the former order of things has been reversed, and that more lives are being destroyed by bullets than by disease.

The types of wounds one saw in hospitals, of course, varied much. Wounds caused by shrapnel greatly predominated. Following these, and perhaps next in frequency, came those caused by machine guns, grenades, infantry rifle, and larger projectiles. Shrapnel wounds and compound fractures were seen most. Bayonet wounds are generally fatal, terminating promptly in death, so that I cannot recall having seen a single wound of this nature.

The parts of the body most frequently wounded are the arms, head, neck, and lower extremities, although shrapnel wounds of all parts of the body are seen.

I saw one soldier who had 157 wounds caused by shrapnel, and these were all over his body. He had lost one foot and a part of a leg, had a permanently stiffened and contracted arm from lacerated and torn muscles and nerve destruction, still he was anxious to get out of the hospital and again serve his country. I was told of another soldier who had received over 300 shrapnel wounds and had recovered. The most helpless lot of wounded one sees are perhaps those with injuries of the spine and cord, with loss of control of both bowel and bladder, and frequently paralysis of extremities.

For these cases radical treatment so far holds out but little hope, and apparently little was being done beyond keeping them as clean as possible and attempting to make them comfortabe. The resort to the use of hand grenades has resulted in the injury and destruction of many eyes. Many eyes have also been destroyed by shrapnel.

I was much impressed with the general results obtained in hospital treatment. The mortality has been low. When one has survived his wound until he reaches a hospital his chances of ultimate recovery, thanks to the skilled treatment and nursing received, are good. I had the opportunity of inspecting the records of a number of the hospitals visited. In one large general hospital with 1300 beds, with an admission of 11,000 cases since the beginning of the war, the mortality was seven-tenths of 1 per cent. from all causes. Another smaller hospital, with some 450 admissions since opening, gave a still lower mortality rate. The death rate in hospitals should be even lower in the future because of the fact that tetanus, which existed among the wounded last fall and winter and caused numerous deaths, has been reduced to a minimum by the timely administration of antitoxin a short time after the wound is received.

Typhoid fever and dysentery, the scourge of former armies, so far are almost unknown in the West. The protection afforded the troops in the field by the timely administration of the prophylactic vaccine, on the one hand, and the results so far achieved on the other by sanitation are simply marvelous. Rules are rigid; a soldier drinking unsterilized water is courtmartialed and punished severely. It

has been demonstrated that men can live in trenches for a prolonged period and still maintain good health if but due regard is paid to the warding off of diseases. So far, also, cholera and typhus fever have not reached the western area of the war, although showing a decided increase in parts of eastern Germany, Austro-Hungary, and Russia, in spite of all that is being done to prevent their spread. When the time comes, as it doubtless will, when it will be necessary to move large bodies of troops quickly from the east to the west, or vice versa, without first having undergone proper quarantine and without the customary disinfection of clothing and individuals, and these troops occupy trenches and camps hastily vacated by the opposing army and left in unclean and unsanitary condition, then will come the grave danger of introducing these diseases among the hitherto healthy soldiers; and this fear on the part of sanitarians was more than once communicated to me while traveling in the war zone. The occurrence of such a condition could only tend to increase greatly the danger of the ultimate introduction of these diseases into the United States.

One method of treatment noted, "the open-air treatment of the wounded," was especially interesting. At Cambridge, England, an asbestos-board pavilion hospital, with wards enclosed only on three sides, with openings protected by louvres for free circulation of air, was erected early in the war.

On the south side the wards had been left entirely open to sun and air, except ordinary sunblinds hanging from the top; at first the building was designed for a limited number of beds, but the success of the open-air treatment was soon so pronounced that the building was extended to a capacity of over 1200 beds. The hospital is open at every point to the sun and air, the two most powerful allies the surgeon can have in dealing with wounds in war. The wounded are transported there frequently direct from the trenches in northern France. The wounds in many instances are septic, having been soiled with earth and mud, and the organisms are those that flourish most in these surroundings. Therefore they have the peculiar characteristics that they can grow only in the absence of air. These organisms are not those with which the surgeon has usually to deal. It was very soon found that to cover such wounds up deeply and treat them in closed hospitals was fatal to the patient.

A surgeon related to me some of his experiences in handling this class of wounds near the front in the early days of the war. The stench in the wards after a few days was awful. In despair the unfortunate men were removed, for the sake of the others, to tents outside, as they thought, to die. In forty-eight hours the wounds had ceased to smell, the surfaces looked cleaner, and, except in a few cases where the organisms were too virulent, the patients recovered. It was thus found that the admission of fresh air to the wounds caused these bacteria to perish rapidly and from a state of appalling sepsis the wound was reduced to one of comparative cleanliness, to the great benefit of the patient. I was shown wounds of this nature which, when admitted to the hospital a short time previously, were septic but had cleaned up in a marvelously short time and were in a healthy condition.

The patients in this hospital also presented a freshness and vigor in their convalescence which are generally absent among those who have been for some time in an ordinary hospital. The pallor and weakness usually noticeable in a man recovering from a serious wound or illness were more or less absent. The conception of the open-air treatment of disease is not a recent one. The idea has of late years been elaborated and practically applied in the adoption of open-air hospitals or sanatoriums for the treatment of tuberculosis, and now the well-thought-out design, equipment, and nursing which distinguish the Cambridge hospital, and its adaption for the treatment of the wounded, are distinct advances in the same direction.

The devastating effects of the constant bursting of huge shells over men in the trenches, even when no actual injury is caused by the flying projectiles, is one of the many unexpected results of modern warfare. Although not actually hit, some of those so exposed suffer for a varying length of time from loss of memory, from eye trouble, ranging from blindness to dimness of vision; loss of sense of taste and smell, impaired hearing, and physical upsets. Some never recover but go on into a marked state of mental decline. Various terms have been applied to this condition, such as "battle shock," "nerve shock," "mental shock," and "wounds of consciousness." Scores of men, both in the ranks and among the officers, while apparently fit to the outward eye, nevertheless suffer in a marked degree from this condition, which perhaps can best be described as "nerve fatigue," as a result of the wear and tear of a war of high explosives. The effects of severe shell fire are very complicated; but it may be said simply that they tend to show themselves in a dazed state which may, on the one hand, be developed with complete unconsciousness or, on the other, lightened till a condition comparable to neurasthenia is observed.

The individual, having passed into this state of lessened control, responds easily to small stimuli; is emotional, at one moment at the height of mental exhilaration and the next in the depths of despair. At night insomnia troubles him, and such sleep as he gets is full of visions of past experiences on the battlefield. The quality of the individual's nerve fibers and nerve cells counts for much when subjected to such strains, and the weaker give way first. The part that heredity plays in these cases is well exemplified. Fully 80 per cent., I was informed, of all of these patients have a neurotic family history. Special hospitals are provided for their care, with quiet, rest, comortable and cheerful homelike surroundings, with the use of electricity, massage, and dieting, and in a few instances psychotherapy.

The effects on the troops of gases when released in large amounts have revealed another demoralizing and destructive agent which the medical officers have to contend with in the present war. Being heavier than air, the gas tends to settle in the trenches and overcomes and kills those who are unfortunate enough to inhale it in sufficient quantity. A favorite way is to discharge it when the direction of the wind is favorable and allow it to be disseminated among the opposing forces in that way. Chlorine gas is the active principle of this gaseous compound and is very destructive to life. Many are killed outright, while others are rendered unconscious, some to succumb later. The irritation caused by the inhaled gas sets up an intense inflammation of the bronchopulmonary tract, and one is literally drowned in his own secretions. Some of those who survive the first serious effects of the gas are left with a chronic inflammation of the respiratory tract. Those who have fortunately inhaled air but slightly

mixed with gas soon recover. I had the opportunity of seeing a limited number of these cases. Protective masks against the gas are now used by the troops.

One still saw in the hospitals soldiers suffering from the results of last winter's exposure in the trenches, such as frost-bitten feet. Conservatism in the treatment of these cases has been the rule, and every bit of the extremity that is possible is saved. Another winter should see far less of such injuries to deal with. The trenches of to-day are places of comparative comfort and luxury as compared to those of last winter. They are now roofed over in many instances, with concrete floors or shelves to stand on, and are drained and properly policed.

The *x*-ray apparatus plays a valuable part in the military hospital of to-day. Even the field hospitals are equipped with portable outfits. No military hospital would be considered complete in equipment without such an apparatus. The large hospitals are supplied with elaborate machines, and they have proved invaluable in the armamentarium of the surgeon in fracture work and in the locating of bullets and fragments of shells. The surgeon in war could not work without it.

I was able to visit a considerable number of hospitals of all classes in the United Kingdom and France, and on the whole I found them thoroughly equipped, some luxuriously so, to furnish every aid and comfort to the wounded and sick. Many of the private improvised hospitals are models of perfection in all departments. One of the best of this class in England is that of Mr. Mortimer Singer, an American by birth at Steventon, near Oxford.

The present war, with the use of high explosive shells, producing frightful wounds, with great destruction of bone tissue, has developed numerous mechanical appliances for the treatment of these injuries. Of these perhaps the two first used are the Balkan splint, for leg wounds requiring extension and suspension, and the hip-brace splint, for wounds of the upper arm. The former consists of a firm wood frame about 3 feet broard and 6 feet high, extending centrally over the length of the bed. The limb is ingeniously suspended by means of a metal splint, cords, pulleys, and weights. This splint first came into use during the Balkan War, hence its name. It has since been improved upon and is now extensively used.

The hip-brace splint is supported from the hips by metal uprights connected with a covered metallic belt. The upright braces are attached at the top to a metal splint strapped to support the upper arm in a horizontal or inclined and flexed position. This splint is also much in use.

A survey of the hospitals visited showed them on the whole to be well supplied with competent doctors and nurses. In fact, some of the hospitals visited had a surplus of both.

The high explosive type of shells now used, causing extensive shatter of bones, with great destruction of soft tissues, will furnish abundant bone and nerve surgery in the countries involved in war for the next ten years, and thousands of the wounded and incapacitated will continue as wards of their respective nations for the remainder of their lives.

The Present Status of the Argyll-Robertson Pupil.—Max W. Jacobs concludes that there is at present no reason to doubt the close relationship between lues and the Argyll-Robertson pupil, although the latter has been seen now and then in non-luetic alcoholics, due, perhaps, to a gliosis.—*Journal Missouri State Ass'n.*

BONIME'S MODIFICATION OF KOCH'S TREATMENT OF TUBERCULOSIS.

By RICHARD COLE NEWTON, M.D.,

MONTCLAIR, NEW JERSEY.

LATE PRESIDENT STATE BOARD OF HEALTH OF NEW JERSEY; CONSULTING PHYSICIAN TO THE MOUNTAINSIDE HOSPITAL.

PERHAPS nothing can be more gratifying to our sense of justice than the reflection that at last the epoch-making labors of Robert Koch, in demonstrating the pathology of tuberculosis and in providing a remedy against it, seem to be about to receive their due mead of appreciation. His gigantic intellect unraveled the fundamental problems concerning this disease which had baffled countless investigators since the beginning of history. The treatment that he devised to overcome it is, we believe, the most efficient yet brought forward, and will presumably never be superseded by anything more efficacious. it can be modified with advantage, as many tuberculin therapeutists have shown, but if the true nature of the disease is now known and the action of tuberculin upon it is rightly explained, it does not seem probable that Koch's ideas will ever be entirely superseded. Practically all writers now agree with him that the crux of the successful treatment of tuberculosis lies in its timeliness, and that the only logical method of handling this great problem is the nearest possible approach to the preventive method. If, by any possibility, we can prevent the spread of the contagion, our efforts, hitherto so inadequate, to banish the great white plague from the earth, may at last be crowned with success. Can any words demonstrate more clearly the great mental grasp of Professor Koch than the following with which he closes his exhortation to treat tuberculosis in its earliest recognizable stage, "only then will the new method have become a genuine blessing for suffering mankind, when it will have come to pass that all cases of tuberculosis are taken early under treatment and the occurrence prevented of advanced, neglected cases which, up to the present, have formed the inexhaustible source of ever-recurring infection."

If then, the greatest intellect which has up to this time turned its best efforts toward the conquest of tuberculosis, understood so well a generation ago the pathology and therapeutics of this disease, why is it that today so much uncertainty and doubt is felt throughout the medical profession regarding Koch's method of treatment? The strange, almost romantic history of tuberculin therapeusis is known of all; yet the rationale of the subject and the technique of the treatment are still almost unknown to the profession at large. For this unfortunate state of affairs there would seem to be several reasons. First and foremost, the great body of medical opinion has not rebounded from the almost unspeakable disgust and disappointment which followed the universal outburst of enthusiasm caused by the announcement that Koch had prepared a certain remedy for tuberculosis. Almost in an instant the whole world, lay and professional, gentle and simple, learned and ignorant, had jumped to the joyful conclusion that the "great white plague" had been conquered at last, and that a disease hitherto considered hereditary and incurable was to be banished from the earth forever. The older members of the profession well remember the disappointment, deep, bitter and lasting, which followed the announcement that the new agent had failed and that no permanent good, but rather evil, had resulted from

its use. The reason underlying this untoward result was simply that neither Koch himself nor his associates really understood the extreme potency of the remedy which he had advocated. He had let the genie out of the bottle and was unable to harness him. Nor could anyone explain then exactly how this new agent was to accomplish its purpose, nor how much harm might be done by improper dosage.

Although Koch recommended what were then esteemed small doses to be given by hypodermic injection, the doses were in reality too large and the intervals between them were too short. He used 1 mgm. of the dried tuberculin in solution as the first injection, followed in a day or two by an injection of 5 mgm., and this was followed in two days more by 10 mgm. The dose seems then to have been raised to 12.5 nigm. and so continued until the patient felt much better or worse. It is easy to understand with our present knowledge why this course of treatment disappointed its advocates; but unless we give due weight to the intensity of the "tuberculin delirium," it is hard to realize the extent of the reaction in the minds of the profession against this form of treatment. No doubt two or three centuries earlier the use of tuberculin would have been forbidden by law. Yet such a prohibition would have been practically superfluous, for only a few of Koch's devoted followers retained their faith in tuberculin. Götsch, Spengler, and probably a few others, who had been associated with Koch, continued to use it, while the body of the profession almost unanimously followed the great Virchow in utterly condemning it. Virchow frightened the medical men of that day by asserting that tuberculin "mobilized" the more or less quiescent bacilli in the system of a consumptive and drove them to the uttermost parts of the body to carry on their work of destruction.

The advanced lesions found in the cadavers of those dead of tuberculosis were said to have been increased if not caused by tuberculin, in much the same way as two hundred or more years before, the lesions of chronic malaria were asserted to have been caused by the use of quinine. Nor in all the succeeding years have certain members of every community ceased to malign the salts of the cinchona bark; so it is not likely that with an apparently good case made out against tuberculin by Virchow and other *savants* we shall cease to be told of its dangers by the prejudiced and the ignorant for many years to come. One medical friend of the writer's, who claims to have been using tuberculin for twelve years, and another who has used it more or less for eight years, are dissatisfied with it, and unite in asserting that they have little or no confidence in the Bonime method of treatment, although neither of them appears to have used it properly. These men remind one of the gentlemen cited by Pottenger, who deprecated the administration of tuberculin, one or more of whom had not taken the temperature of their patients either before or after the injections of tuberculin, and at least one other who never examined the chests of his patients, and did not seem to know whether they had tuberculosis or not. It goes without saying that whatever the merits of any plan of treatment may be, only those who have mastered its technique are entitled to pass judgment upon it, and it is naturally a great drawback to the successful administration of tuberculin at the present time that so few men are competent to handle so powerful and so insidious a remedy. Probably no one who has not enjoyed at least six months thorough clinical and didactic teaching on the subject, and who is not in addition a practised and reliable physical diagnostician, should attempt to use tuberculin by the Bonime or any other method.

However, to return to the history of the present revival of Professor Koch's treatment, we observe that it was finally pointed out that the lesions found in the bodies of those dead of tuberculosis were much the same whether tuberculin had been administered as a remedy or not. And as time went on it was ascertained that of all the patients treated with tuberculin in Koch's clinic, quite a fair proportion had recovered their health, so that the disease in their cases at least had been arrested and the fearsome remedy had done them no permanent harm. Some of these patients are living to-day. As intimated before, Spengler, Götsch and other *savants* who had worked with Koch, never lost their faith in tuberculin. After using graduated doses for ten years, Götsch, at Koch's suggestion, published his results which showed that his cases had done better than could have been expected without the use of tuberculin. Some of the best minds in the profession then began to realize that the remedy had been condemned too hastily. In America Dr. Trudeau is said never to have lost his faith in the ultimate triumph of this form of medication. Gradually step by step the value of a judicious use of tuberculin has been wringing a more or less reluctant assent from the profession, and the end is not yet.

Neither so far does there seem to be any revival of the "tuberculin delirium" of Koch's time, and this is as it should be, for, as Dr. Baas delights to remind us in his History of Medicine, nothing in medical progress that meets with instant and uproarious approbation turns out to be of permanent value. And while human nature remains as it is, and always has been, it is far better that there should be sufficient opposition to the introduction of such a remedy as tuberculin to force its advocates to be very sure of their ground. If each step of the advance be stubbornly contested false, extravagant and misleading claims will be checked in their incipiency and the true status of the new agent will be the sooner and the more firmly established.

Just now tuberculin is not one of the medical fashions in America, and for reasons to be given later we hope that it never will be so fashionable that any one except a real expert will ever consent to use it. Its injudicious use, even in Koch's hands, was unavoidable thirty years ago when it was so little understood. Now, however, its onward march is steady and its advocates are ready to give reasons for their faith and to show their cases.

In America Pottenger has worked with tuberculin twenty-five years. He says that between two of his comparatively recent visits to Germany, a period of three or four years I believe, he observed that the percentum of the tuberculosis sanatoria using tuberculin treatment had risen from twenty-five to about seventy-five. Ritter was converted from an opponent to a strong advocate of this treatment by his experience in his own institution, where he began (probably in desperation) to treat the most unpromising cases such as had been excluded from the public (insurance) sanatorium or had already undergone an unsuccessful course of non-tuberculin treatment.

Dr. Bennett says (in *The Practitioner* for Jan., 1913) that when he began treating tuberculosis with

tuberculin he could not banish from his mind the fear of the injury which the remedy might do the patients, and continues, "The first few weeks did nothing to remove this feeling, but as soon as I abandoned all attempt to hurry matters and was content to make the treatment reactionless, the feeling of opposition died away and I now feel quite convinced that tuberculin is of the very highest value in the treatment of the disease." This able practitioner had used tuberculin in fear and trembling for some years until the light broke upon him that he should no longer try to abort or drive out a constitutional disease in a few days. In other words that he should not try to force nature's hand, but should humbly study and carefully follow her methods and she would do her part by gradually but surely healing the sufferer from a disease which had been generally regarded as hopeless. The *Journal of Vaccine Therapy* for September, 1913, after summarizing a series of cases, says editorially: "No ill effects were traceable to the tuberculin. The chief danger in the administration is, we think, an impatience on the part of the immunisator," who has ever to contend with the obsession, so common in the lay and often in the professional mind, that the larger the dose the greater the benefit. Our editor goes on to remark that one would not endeavor to raise a patient's toleration to strychnine to a thousand times the initial dose, and yet tuberculin is to a non-immunized tuberculous patient a more powerful drug than strychnine.

Tuberculin, while it is innocuous to a non-tuberculous person, will, by dissolving the capsules of the tubercle bacilli, already present in the body of a tuberculous subject, set free certain toxins. These must be neutralized by the appropriate antibodies or they will do serious harm. These antibodies are secreted by the body cells under the stimulus of the toxic action of the bacilli. However, only a limited number of antibodies can be produced at once, and if the dose of tuberculin is too large, even very slightly so, too much toxin is liberated and harm is done. As Professor Park puts it, "we have the paradoxical condition that the (bodily) mechanism associated with protection is also the mechanism of intoxication when over-developed or over-active," or, as other writers (*e.g.* Riviere, Morland, Rosenau and others) put it, the hypersusceptibility is necessary for the production of immunity, and these two opposing states are interactive and mutually dependent.

Hence, our guiding principle in tuberculosis therapy is to stimulate sufficiently, if possible, but never to overstimulate the hypersensitive body-cells. If our stimulus is insufficient, we shall produce a state of allergy without accomplishing our object. This we may also do by too soon intermitting the treatment. We are treading on dangerous ground and must always be guided by the motto that haste makes waste. The action of tuberculin injected into the tuberculous body may illustrate the whole process of the disease. The consumptive patient is constantly producing antituberculin to combat his autoinoculation, as has been shown by the complement deviation test by Bordet and Gengou. So long as his body cells can keep up this supply of defensive agents the disease does not gain appreciably. Sometimes the bacilli are entirely routed and the patient regains his health. Often, however, these invading bacilli are driven into retirement and may not reappear for years. In childhood glandular and joint lesions are frequently arrested, and in adults pulmonary lesions are also frequently, but not generally, recovered from. This shows how long and how hard nature fights to subdue and expel the invader, and how beneficial a little help at the right moment may be. The sooner we can give the help the more chance there is that nature, properly reinforced, will conquer. Babies having practically no antibodies are extremely susceptible to the deadly action of the bacilli. If, however, we can even partly tuberculize them before they succumb to the invasion it seems probable that they will produce sufficient antibodies to free their system from tuberculosis for the rest of their lives. An intercurrent infection, like measles, seems to completely banish hyper-susceptibility just as an overwhelming auto-intoxication may do, so in a way that we do not comprehend our principal line of defense may be completely thrown down and acute general miliary tuberculosis may supervene. These conditions, so crudely sketched, seem to me to indicate, not alone the necessity, but the eminent advantage of using tuberculin in a proper manner. Just so long as the body cells are able to react to tuberculin, just so long more antibodies will be thrown out and the patient's general condition will be improved and some advanced cases will be cured. In like manner we see an occasional recovery in a patient who has been treated by the ordinary methods, apparently without avail, and who has been sent home to die, when far advanced in the third stage of consumption. In this patient the bodily forces have finally overcome the invader by the production of a state of complete immunity. So with tuberculin we may, and frequently do, in apparently hopeless cases, produce at last a state of complete immunity to the poison of the bacillus. It would, however, be unreasonable to expect to produce such a state in a majority of third stage cases.

Now, how shall we administer this remedy? Without taking the time to discuss the various tuberlins and their method of administration, let us take up the consideration of what promises to be a feasible and efficient method in all cases. I refer to a method devised by Dr. Ellis Bonime of the Polyclinic Medical School and Hospital, and practised by him for a number of years. In cases that show unmistakable symptoms of any form of tuberculosis and in some doubtful cases no diagnostic doses of tuberculin are necessary. But in many cases a diagnosis must be made and is impossible without the subcutaneous use of tuberculin. The von Pirquet test, which is so easy to apply, is not of much value after the first year of life. Although if it be negative when properly applied and repeated once, there is a strong probability that the patient is not tuberculous.

The only positive test is the subcutaneous injection of the proper dilution of O. T. Starting in cases of suspected pulmonary tuberculosis with .10 cc. of No. iv dilution, and taking the temperature every two hours in the twelve hours succeeding the injection, if there be no reaction in 48 hours .50 c.c. of No. iv is given; if no reaction follows this, give .10 c.c. No. iij; if this has no reaction .50 c.c. of No. iij. Then .10 c.c. No. ii; then .50 c.c. No. ii, and finally .10 c.c. of No. i. If, after these five injections, given every 48 hours, no reaction occurs, the patient is non-tuberculous. In giving the injections a sharp, perfectly clean needle should be used. The needle should be passed in parallel to the skin into a spot on the outer aspect of the upper arm that has been previously painted with iodine.

No covering of any sort is needed over the site of the injection, although some practitioners prefer to paint the spot with collodion. The so-called "Record" syringe, imported from Germany, is the proper one to use, although there are fairly good syringes of American manufacture.

The determination after dosage is the next step in the procedure. Dr. Bonime has not used logarithms or involved mathematical formulæ to regulate his doses. He leaves nothing to chance. He declines to treat a case where he cannot have reliable temperature records. The increase of his dosage is in arithmetical progression, not in geometrical progression, which was formerly largely used and was unquestionably very harmful. He repeats each increase once. He dilutes the tuberculin with ½ of 1 per cent. phenol in sterile normal salt solution. He uses preferably Koch's old tuberculin made into six or more dilutions, each one a decimal of its predecessor. This formula has been recommended by Park and Williams and others, and is not new. The selection of the appropriate dilution to each case calls for the best judgment and clinical experience. Dr. Bonime protests vigorously against routine and rule of thumb methods. Only an experienced clinician and tuberculin therapist is competent to select the appropriate dilutions for each case, as it comes along. A mistake here may vitiate and render abortive the entire course of treatment. In a general way experience has demonstrated that closed glandular tuberculosis should be started on No. iii (dilution 1-1,000), but open or postoperative cases should be started on No. iv (dilution 1-10,000) because of their increased susceptibility. Closed pulmonary cases should be started on No. iv, whereas open pulmonary cases should begin on No. v (1-100,000) or No. vi (1-1,000,000). But there will prove to be many exceptions. Each case must be individualized and its needs and limitations carefully determined, as *e.g.* colored people and Italians are more susceptible than others and should be started on the dilution next higher than that used for most Caucasians. We should never forget that we are instituting a course of treatment of a hydra-headed and treacherous disease which may pervert every one of the bodily functions and attack every one of the bodily organs.

As explained above, our main hope, in fact, in tuberculin treatment, our only hope of success, is so to marshall and direct the forces of the patient's own body that they will repel the invader and shake off the insidious and slowly developing infection, which may have maintained itself alive, albeit inactive, in the tissues for months and years, stealthily awaiting the time when the bodily defenses shall be relaxed so that the invading forces may begin their ruthless march of destruction.

Having begun the administration of the selected dilution of O. T., Dr. Bonime increases his initial dose with the utmost caution, using at first .10 c.c.of the selected dilution. He increases this by .02 c.c. after a three or four-day interval. The next hypodermic injection will be another increase of .02 c.c., making .14 c.c. The next increase will be by .04 c.c., which will be repeated once. Then .06 c.c. also to be repeated once. The injections are made twice a week in the late afternoon or evening, and the increased dose should precede the four-day interval, as the larger interval lessens the probability of a reaction.

Reactions must be avoided at any cost, and the immunizator should never forget that he may undo weeks of good work by a little carelessness. Thus he should be especially particular about the needles and syringes used, and in the observation of strict antisepsis in making the injections.

The general scheme of treatment is as follows, beginning, let us say, on Monday at 8 P. M. Suppose the case to be one of "closed" pulmonary tuberculosis.

We give on

Mon.....	.10 c.c.	No. iv	Increase .02 c.c.
Thurs.....	.12 c.c	No. iv	
Mon.....	.14 c.c.	No. iv	Increase .04 c.c.
Thurs.....	.18 c.c.	No. iv	
Mon.....	.22 c.c.	No. iv	Increase .06 c.c.
Thurs.....	.28 c.c.	No. iv	
Mon.....	.34 c.c.	No. iv	Increase .08 c.c.
Thurs.....	.42 c.c.	No. iv

Etc., etc.

A reaction is indicated by a rise of temperature of one or more degrees Fahrenheit (occurring during the second twelve hours, after the injection), above the usual temperature of the patient as shown by the recorded temperatures for that hour of the day. It has been found, so seriously in earnest are all consumptive patients to get the upper hand of their disease, that they or their friends can be relied upon to take and record their temperatures as often as may be required. Naturally, rectal temperatures are to be insisted upon. Even school children can be excused to go to the toilet every two hours to take their temperatures.

Most of the cases in Dr. Bonime's clinic are ambulatory and home talent must be depended upon to keep the temperature records. It is rather surprising to note how well most of these patients learn to do this. Sutherland says in the *British Medical Journal* for Sept. 16, 1911, that "it has been demonstrated that eighty percentum of the early cases of tuberculosis can be treated at their own homes without interference with their occupation." We have no space to discuss here the economic advantage of this proposition. Generally speaking of course, the help of competent nurses or young physicians for follow-up work would be very great.

Dr. Bonime requires four hour temperatures daily while his patients are undergoing his treatment; and on the days succeeding the injections of tuberculin he has the temperature taken every two hours. This is done for the purpose of detecting a reaction. Should one occur, the treatment must be suspended for a week and not resumed until after every symptom of constitutional reaction has subsided. Then the injection of tuberculin should be that of the third previous dose. To illustrate; if on a Tuesday a reaction shall follow the injection of the preceding Monday which was, we will say, .50 c.c of No. iv dilution, no injection is given until the Monday following the dose that caused the reaction, then the dose would be .34 c.c. No. iv solution. No reaction will probably follow. Then the gradual cautious approach to a saturating dose will be resumed and the increase of .02 c.c. of the solution will be adopted (each increase to be repeated once) so that on the next Thursday .36 c.c. not .42 (as in the original schedule) will be given. Then on Monday following .36 c.c., etc., so that it will be

three and one-half weeks before a dose as large as the dose that caused the reaction will be again reached. Fortunately the reactions that do occur in this method of treatment are so small, the high temperature sometimes lasting only a half hour, that they do little harm and are frequently, if not generally, unaccompanied by any perceptible symptoms except the temperature increase. Hence the necessity for the two-hour thermometric observations during the second twelve hours after the tuberculin injections.

When the patient has been safely conducted through the various dilutions and has reached that stage of immunization that he will not react to 0.1 c.c. pure O. T. This is to be followed in a week by .20 c.c. pure O. T. then if there be no reaction Dr. Bonime switches him onto bacillary emulsion (B. E.). This he considers imperative in joint cases and highly desirable in all cases of tubercular infection. Because the B. E. will immunize the patient against certain products of the infection which are more or less refractory to the action of O. T. The same decimal dilutions are made of B. E. but for the patients having passed safely through the injections of O. T. only dilution No. i, of B. E. is used. When using B. E. the intervals should be doubled, since it takes longer for the neutralization of the larger percentum of toxin contained in the B. E. than in the O. T. Beginning with dilution No. i of B. E. it is customary to increase by tenths of a c.c. given weekly through this dilution. When 0.1 c.c. pure B. E. has been reached without reaction, the intervals are extended to three months. If the patient can take, without reaction 0.1 c.c. pure O. T. four times in a year, he is presumably immune from infection with the T. B. although under certain circumstances as *e.g.* an attack of measles, this immunity may be broken down and the state of hypersusceptibility may recur and another course of tuberculin treatment may be necessary to restore the patient's immunity. Beginning, usually with No. i O. T. and continuing as before.

A course of Dr. Bonime's treatment may last from four to eighteen months, but the average duration of a sanatorium course of treatment leading to a complete arrest of a tuberculous process is two and one-half years, and of these arrested cases, at least 30 per cent. relapse and die of tuberculosis.* Whereas, it is agreed by practically all of the authorities of the present time that all cases having had a thorough course of tuberculin are more resistant to tuberculous infection than those who have not been so treated. I am not aware of the existence of any statistics covering the above mentioned point, although it is to be hoped that some will soon be available.

It is hardly necessary to observe that ambulatory patients who have been able to maintain themselves and their families and have kept away from the enervating influences of a sanatorium are in a far better fix to maintain their improved condition and their place in the world than if they should return from sanatorium conditions and again try their luck in the unfavorable surroundings where they developed their original tuberculosis.

This paper is already too long and no space is left to speak of joint and grandular tuberculosis, and the treatment of mixed infections. For the minutiæ of the therapeusis of these phases of tuberculosis the reader is referred to Dr. Bonime's forthcoming book and to a paper by Dr. Sidney Twinch of Newark, read in the orthopedic section of the recent Congress of American Physicians and Surgeons, giving a series of forty-five or fifty joint cases, some of whom had resisted the routine treatment for years and all of whom have been cured or greatly benefited by the Bonime treatment.

If Dr. Pottenger can report an improvement in his results of from 20 to 25 per cent. more cures of tuberculosis under tuberculin treatment than where the dietetic-hygienic treatment alone was employed, and if certain tuberculin clinics in England and Germany can report 100 per cent. of cures in the early stages of tuberculosis by the judicious use of tuberculin, we believe that we shall see still better results in all cases of tuberculosis by the simpler, safer and more exact method of treatment taught us by Dr. Bonime.

As Dr. E. Mariette (*Brit. Med. Journal*, Sept. 16, 1911) strongly puts it "The results claimed by German writers, which are confirmed and endorsed by those who have used their methods in this country, ought to be sufficient to convince every practitioner in charge of an uncomplicated case of phthisis, that if he withholds from his patient the benefits of a thorough course of tuberculin he is almost as guilty of culpable negligence as he would be in performing an operation without due antiseptic precautions."

42 Church Street.

*The annual report for 1915 of the Rhode Island State Sanatorium for Tuberculosis gives the death rate of their discharged cases for the past ten years at 57 per cent. of 2142 patients. This is the entire number which it has been possible to trace.

THE RELATION OF TUBERCULOSIS OF THE BRONCHIAL GLANDS TO THE DIAGNOSIS OF TUBERCULOSIS OF THE LUNGS.*

By MARY E. LAPHAM, M.D.,

HIGHLANDS CAMP SANATORIUM, HIGHLANDS, N. C.

Tuberculosis of the bronchial glands may cause tuberculosis of the lungs in three ways: by representing the primary focus of infection whence supplies of tubercle bacilli may be transported to the lungs at any time; by direct extensions of tuberculous processes from the glands surrounding the root of the lung; by pressure upon the trachea and bronchi which induces such secondary pathological changes in the lungs as to favor the development of tuberculous processes.

From this point of view, the diagnosis of tuberculosis of the lungs may begin with that of the bronchial glands and we should never say that there is no danger from tuberculosis until we have proven that there are no tuberculous processes in the bronchial glands. After we are confident that there are no physical signs in the lungs suggesting tuberculosis we must remember that it is equally important to determine whether there are any tuberculous processes in the bronchial glands or not and if there are, then the problem is how to estimate their effect upon the lungs when we have no physical signs to guide us.

There are two reasons for not finding tuberculosis of the lungs when it already exists: there are no physical signs or we find pathological conditions which are common to non-tuberculous diseases of the lungs, and because these conditions are of such long duration we take it for granted that they cannot be tuberculous.

*Read at the meeting of the National Society for the Study and Prevention of Tuberculosis, Washington, May 12, 1916.

When tuberculous processes extend from the hilum into the lung, it may not be possible to detect them by a physical examination and there is no analogy between the diagnosis of the apex or the pleura or other peripheral parts of the lungs and these creeping, thread-like peribronchial infiltrations which give no sign of their presence. It is possible to say with more or less accuracy that the upper part of the lung is involved to such or such an extent by depending upon physical signs, but this is not true of the infiltrations extending from the hilum into the lung because the tissues are not impacted, there is not the infiltration en bloc, the physiological function of the larger bronchi is not altered, there is the same content of air, the intima is not roughened, the breath sounds are not changed and there is no dullness, so that we have nothing to inform us of the first act of the tragedy being played in the lungs. A theoretical consideration of the pathology of these peribronchial extensions shows us when to expect their revelation by physical signs and when not.

Enlarged tuberculous glands surrounding the root of the lung threaten its integrity in two ways: first by pressure upon and interference with the return circulation of blood and lymph from the lungs; second, by direct extensions by contiguity because these glands lie so close to the lung that as Osler has said it is sometimes very difficult to say where the lung tissues end and the glands begin. Kraemer has compared the effects of the pressure exerted by these enlarged glands upon the return circulation from the lungs with those caused by enlarged cervical and inguinal glands and suggests that just as they cause edema and dilatation of the veins of the face, neck, external genitalia, and lower extremities, so the enlarged glands at the hilum cause stasis and edema of the drainage territories adjacent to them.

Remembering that the network of vessels surrounding the alveoli would cover 150 square meters of surface if spread out on the floor, and that all their immense content must be returned through the relatively narrow portals of the hilum, it is quite possible that a slight amount of pressure at the hilum might produce a disproportionate amount of obstruction which would congest the nearest areas of drainage which in the right lung would be the upper part of the lower lobe, the middle lobe, and the lower part of the upper. This edematous condition might easily cause effusions into the interlobar fissures with subsequent plastic absorption and scar formations. Edematous infiltrations of the tissues surrounding the hilum would be more apt to cause dullness and altered breath sounds if there were not such an excess of large air passages over smaller that the air content was preserved over that lost. The exaggeration of the breath sounds into something like bronchophony may be caused by the pressure imparting a better carrying quality to the walls of the bronchi and this and d'Espine's sign of increased transmission of the whispered voice are often the only and most reliable physical signs obtained from tuberculous processes in the bronchial glands. The pressure upon the bronchial circulation, the tendency to suffusion, to slowing of the currents, to subsidence of their contents, and to a backward wash out of the bronchial glands favor the gradual extension of tuberculous processes through the sheaths of the larger bronchi and on point by point to the smaller ones. Leaving the regions surrounding the hilum and tracing these peribronchial infiltrations on their way through the lung, we find that there are no physical manifestations of their presence until they reach air passages which are not sufficiently rigid to resist their pressure; up to this point they have not affected the interior of the bronchi, but have remained purely interstitial and inert; there is no attack and no defense; like foreign bodies they are fibrosed as fast as deposited and no harm is done because there is no toxemia, no absorption, and no liberation of toxins. These fibrosed processes are more like lichens stretching along the limbs of trees than disease producers. Coming to the smaller and softer air-passages with no cartilages to keep them open, they collapse, the air cannot enter so freely, the breath sounds are weakened, and the lobules are not filled sufficiently to expand them promptly anad vigorously; insufficient breath sounds and insufficient expansion of the alveoli are the characteristic consequences of pressure upon the smaller air-passages. There is no reason for altered breath sounds, for harsh or granular breathing or for any of the signs of disintegration; nor is there any dullness, for the air content of the larger bronchi is preserved. It may even be that instead of dullness there is an increase of resonance suggesting emphysema. Even in the long, thin, flat chest with little or no motion in the intercostal spaces; even when the lung is so tied down that the chest rises and falls as a whole *en cuirasse*, we may find to our surprise that not only is there no dullness but actual hyperresonance in some regions. Resonance characteristic of an excess of air, of emphysematous conditions. It is possible that the walls of the larger bronchi are rigid with their infiltrations and so do not expel their air as they should and that the retained air more than compensates for the loss in the terminal lobules. It is possible that we have a bronchitic emphysema which is comparable to the alveolar form and produces the same lack of collapse and expansion with the same insufficient exchange of air and suppressed breath sounds. As one by one the terminal areas are choked off, the leaves or the breathing spaces of the bronchial tree are obliterated, they collapse, form atelectatic areas, and the lung is tied down. Thus one lobule after another disappears until finally the branches chiefly remain and the breath cannot get much beyond the bronchi. This is fibroid phthisis *par excellence* without breaking down, without disintegration, without absorption of toxins. As the rigidity of the bronchial walls increases they cannot stretch and follow the expanding chest wall so that the thorax is drawn in eventually and there is dimpling over the hilum and in the second and third intercostal spaces near the sternum. But all these evident manifestations come too late; what we need is detection as these infiltrations begin to creep from the hilum along the main bronchi through the paravertebral region on up to the apex, or through the subpleural spaces out to the axilla, or downwards towards the base. When the lobules in the apex collapse we can discover it; when half an inch or more of normal lung substance in the cortex covers up the deeper extensions, how can we detect them by physical signs? The pathology of these peribronchial extensions teaches us not to depend upon physical signs because we cannot obtain them; not to expect the signs of pneumonic infiltrations because the tissues are not infiltrated compactly; not to look for disintegration because there is no break-

ing down; not to rely upon harsh or granular breathing or rales of any kind, but rather to seek for indications of gradual obliteration of the breathing spaces in the terminal lobules. Applying the ear directly to the skin we notice that, as we feel the chest wall pulled out against it, we cannot hear the accustomed response of the entering air; instead of the rush of the air through the air-passages and the prompt and uniform unfolding of the alveoli, we hear little or nothing; it is rather as if some stupor robbed us of our keenness of perception; as if our senses were dulled; as if a veil were drawn across between us and the lung; all is dulled, blurred, obscured, suppressed, just as the nature of the pathological processes would lead us to expect.

The pressure from enlarged tuberculous glands surrounding the trachea and bronchi produces different effects upon the lungs from those caused by the glands at the hilum. When these glands enlarge and press upon the walls of the trachea and bronchi, circular constriction does not so much follow as a flattening or lateral thrusting in which narrows the lumen aand causes tracheobronchial stenosis. In the beginning this stenosis does not obstruct the entrance of air because inspiration distends the air passages as the chest wall is pulled out and the stenosis is relieved; the entrance of air is also furthered by the weight of the atmosphere pressing down upon the column of air reaching from the upper air passages to the alveoli and forcing it down upon the retreating alveolar walls. As the chest wall falls back the lumen of the air passages is compressed, the stenosis returns, and now the column of air driven upward by the collapse of the lung meets the stenosis and the weight of the atmosphere is against its escape. Delayed and difficult expiration results with retention of air distal to the stenosis; as the bronchial glands enlarge and the pressure increases, the difficulty of getting rid of the accumulated air becomes greater until finally expiratory dyspnea results; gradually the intra bronchial and intra-alveolar pressure from the retained air increases and the essential features of asthma appear with more air entering the lung during inspiration than can be easily expelled by expiration, and attacks of expiratory, asthmatic dyspnea develop; with increasing accumulation of air and rise of intra-alveolar pressure, emphysema follows; if the backward thrust of the air against the stenosis is sufficiently great to force the wall of the bronchus out, there is bronchiectasis and expectoration of profuse, purulent sputum which as a rule does not contain tubercle bacilli; if the entering force of the column of air is not sufficient to distend the smaller air passages, they collapse and form areas of atelectasis; these atelectatic areas are especially apt to form in the lobules and to constitute the acinous-lobular type of infiltration. Irritation at the point of pressure and interference with the bronchial circulation cause hyperemia, inflammation of the mucosa, exudations, and chronic bronchitis which may persist for years. The congestion of the vessels in the bronchial walls may cause rupture with hemoptysis and hemorrhages occurring at intervals and persisting for years. The irritation of the bronchi establishes a tendency to catching colds and repeated attacks of bronchitis. A cough may persist for years annoying and paroxysmal or so insignificant as to escape notice; dry and hard when due to pressure on the vagus, wet and easy when due to catarrhal conditions. As a consequence of tracheo-bronchial stenosis there are secondarily induced in the lungs diseased conditions similar to those of bilateral, chronic, diffuse bronchitis, asthma, emphysema, bronchiectasis, and atelectasis, together with hemoptysis and hemorrhages. In these cases of tuberculosis of the lungs secondary to tuberculosis processes in the bronchial glands, we cannot depend upon physical examinations of the lungs for sufficiently reliable information to positively exclude the presence of danger. Before we can conscientiously give the verdict, no tuberculosis of the lungs because there are no physical signs, we may be forced to seek the aid of tuberculin and the Roentgen ray.

The tuberculosis of bronchial glands is closely associated with the diagnosis of those cases of incipient tuberculosis which cannot be revealed by physical signs.

The child has a cough, or does not gain in weight, or is not strong. The adult is not quite up to par—does not feel just right; has an innate conviction that something is wrong; cannot say just what it is—but he is worried and anxious about himself: There is not enough vigor, or he does not sleep well or is very nervous. How many of these cases are dismissed with the comforting assurance that nothing is wrong? That the child is all right and the man tired or neurasthenic? Take a little vacation or go out in the country for a few days and you will be all right. There is absolutely nothing to worry about—there is nothing in the lungs.

In these cases with clinical suggestions of tuberculosis which cannot be confirmed by physical findings in the lungs, before assuring the parent or patient that there can be no tuberculosis because nothing can be found in the lungs, we should remember that it is very possible that we are dealing with tuberculosis of the bronchial glands which may some day cause tuberculosis of the lungs and that to discover pulmonary tuberculosis effectually in its very incipiency we may have to begin with that in the bronchial glands.

A NEW METHOD OF EXTIRPATION OF THE LACRYMAL SAC WITHOUT RESULTANT SCAR.

By J. A. KEARNEY, M.D.

NEW YORK.

LECTURER ON OPHTHALMOLOGY, NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL.

No visible facial scar may be assured the patient who submits to the operation for the removal of the lacrymal sac by way of the slit canaliculi.

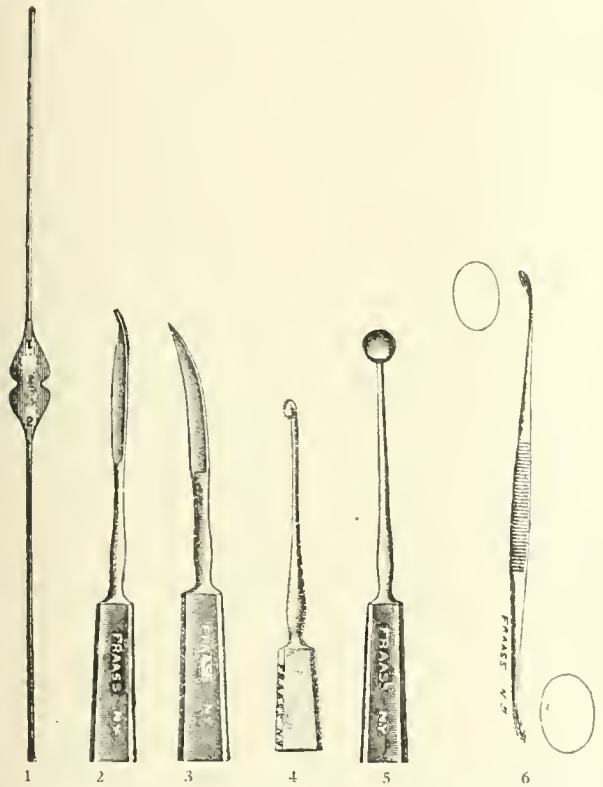
Most ophthalmic operators have experienced great difficulty in obtaining the patient's consent when a suggestion to remove the sac through a facial incision with a certain scar remaining of uncertain dimensions, but little or no resistance is offered by them to the operation promising as good result without a scar. Especially is this the case with women. Where there has existed for a time an annoying chronic dacryocystitis of either the catarrhal type, with regurgitation of mucoid secretion into the conjunctival cul-de-sac, or the recurrent phlegmonous type, the extirpation of the lacrymal sac becomes imperative, and the patient is confronted with the choice of operation.

It is possible to do this operation with a local anesthetic injected into the skin about the sac, but

it is much more satisfactory to administer complete anethesia, preferably ether.

The conjunctival cul-le-sac is flushed with a saturated boric acid solution after the contents of the lacrymal sac are milked into it. Bowman's Number 1 probe is passed through each canaliculus as far as the bony wall; this dilatation allows the engagement of the tip of a Weber's knife, which is passed down the upper canaliculus, making the usual Bowman slit, then down the lower one in the same way. There usually remains a bridge of tissue between the distal ends of the incisions. This is severed with a curved bistoury. The anterior lacrymal crest is then located and the internal canthal ligament is divided at its insertion here.

The diseased sac and the surrounding granulomatous tissue and the bone beneath, when found carious, are then broken up by the appropriate curettes and scraped out through the original incision. The walls of the canaliculi are scraped also. The



1 2 3 4 5 6

Instruments used: 1, Bowman's No. 1 probe; 2, Webber's canaliculus knife; 3, curved bistoury; 4, 5, 6, special sac curettes.

cavity is then cleansed with a swab saturated in bichloride of mercury solution (1 to 500). A thick pad of cotton wrung out of saturated boric acid solution is placed over the operated area and a head bandage is applied firmly over it so as to produce pressure sufficient to keep the walls opposed and prevent swelling.

The after-treatment consists of cleansing of the conjunctival cul-de-sac and the renewal of the bandage daily for three or four days.

The advantages of this operation are: (1) There is no scar remaining on the face; (2) there is less difficulty in obtaining consent to operate when no facial scar is assured; (3) there is much less hemorrhage during the operation; (4) there is no possible return of the condition, because the mucous lining is ablated from the puncta to the upper portion of the nasal duct.

Conclusions as to results: (1) Cessation of all sac secretion immediately after operation; (2) epiphora diminishes gradually and finally ceases.

Case I.—A. C., an Italian boy aged nine years complaining of severe pain over the lacrymal sac area on the right side. Eye was closed, the tissues in this region were deep red and swollen to the size of a small walnut. There was no sign of pointing; epiphora was only slight. August 20, 1913 ether was administered. Dr. W. H. Long of Philadelphia, assisted. Bandage applied for four successive days. There was a gradual reduction of the redness and swelling. At the end of three weeks there was no discoloration of skin or epiphora.

Case II.—A brother of Case No. 1, aged eleven years, suffering pain over the right lacrymal sac; this region was red, slightly swollen, and a fistulous opening existed in its lower portion. Epiphora not annoying. There was a history of a few previous attacks. August 20, 1913, ether was given. Dr. W. H. Long assisted. Bone was found carious. Fistulous opening was scraped and bandage applied. At the end of four weeks there was no redness and with difficulty the previous site of the fistula could be found. There was no epiphora.

Case III.—J. McD., aged ten, a son of Irish parents, complaining of tears overflowing and at times a thick secretion filling the left eye. The skin was elevated over the lacrymal sac area (mucocele) and pressure here expressed a mucoid secretion through the puncta filling the conjunctival cul-de-sac. August 29, 1913 ether was given. Dr. W. H. Long assisted. Bone was found carious; bandage applied for four successive days. There was no reaction observable at any time after the operation. At the end of four weeks the epiphora was lessened considerably. At the end of eight weeks the epiphora was only slight occasionally outdoors and none at all indoors.

Case IV.—T. G., a son of Irish parents, aged ten, complaining of pain over the lacrymal sac area of the right eye. A recurrent phlegmonous attack of dacryocystitis. No complaint of epiphora. August 7, 1913 ether was given. Dr. W. H. Long assisted. The bone was found carious. Bandage kept on for five days. At the end of five weeks there was no epiphora, no pain, and no discoloration of skin.

Case V.—Mrs. A. L., an Italian woman, aged thirty-two, consulted me because the tears overflowed and the conjunctival cul-de-sac of the left eye filled occasionally with a thick viscid secretion. There was no mucocele, but pressure over the sac area caused a mucoid secretion to fill the cul-de-sac. She gave a history of probing and treatments for the past three years. May 14, 1914, ether was given. Dr. B. L. Gordon of Philadelphia, assisted. Bone was found carious. Bandage applied and renewed daily for five days. One month after the operation, no secretion and epiphora lessened. At the end of four months there was no epiphora indoors and only occasionally outdoors.

Case VI.—Miss L. R., a Jewish woman aged thirty, consulted me because of a thick secretion filling the left cul-de-sac and epiphora. The secretion blurred her vision occasionally and she begged for relief. She gave a history of this condition lasting about five years, during which time the lacrymal passages were probed and medicated. June 16, 1914, ether was given. Dr. B. L. Gordon assisted. Bone was found carious and bandage applied. There was no reaction observable after the operation at any time. At the end of eight weeks there was no secretion and no epiphora.

Case VII.—Miss A. B., aged twenty-five, a daughter of Irish parents, complaining of a thick secretion in her right eye and overflowing of tears so annoying that it interfered with her work. Skin was distended over the sac (mucocele) and when pressed the glairy fluid filled the cul-de-sac. August 16, 1914, ether was given. Dr. Austin O'Malley of Philadelphia, assisted. No carious bone found. Bandage applied. Next day there was no reaction. Bandage removed in three days. Eye looked well. Went back to work the fourth day after the operation. The epiphora lessened a great deal at the end of the first week. At the end of three months the tears did not seem to bother her much indoors and only slightly outdoors. At the end of six months there was no epiphora at any time.

Case VIII.—Mrs. B. B., aged thirty-five, a Jewish woman, suffering from a recurrent attack of plegmonous dacryocystitis on the right side. Had had three or four previous attacks and wanted relief. Ether given September 18, 1914. Dr. B. L. Gordon assisted. Carious bone found. Bandage applied. Redness and

swelling gradually disappeared. She had no annoying epiphora at any time. One month after the operation she was entirely well.

Case IX.—An Italian woman presented herself for treatment in my service in the eye dispensary in the Polyclinic Hospital, New York, with the tissues red and swollen over the right sac area, complaining of great pain. There was some epiphora. She gave a previous history of thick secretion in her eye and probings and treatments of the lacrymal sac. August 26, 1915, cocaine injected into the skin surrounding the sac. Dr. T. A. Northcott assisted. Bone found carious. Bandage applied. Case observed every other day. The discoloration disappeared at the end of one month. The tears were still annoying. At the end of four months there was no epiphora.

Case X.—A German woman, aged forty-five, applied for treatment, in the eye dispensary of the Polyclinic Hospital, New York, in my service, with an annoying glairy secretion in the left cul-de-sac and epiphora also. She had been probed and medicated for five or six years previous without results. September 25, 1915, cocaine injected into the skin about the sac. Dr. P. A. Cavanaugh assisted. Bone found to be carious. Bandage applied. The bandage loosened during the night. The next day over the field of operation the tissues were swollen and the wound gaped. Bandage reapplied. Swelling disappeared slowly. The healing took place from the bottom of the wound. Opening cleansed daily and at the end of two months the walls of the wound were adhered. Bandage applied daily during this time. At the end of three months there was no sac secretion and the epiphora lessened a great deal. At the end of four months the epiphora was present only in the wind.

Case XI.—An Italian woman, aged forty-five years, applied for treatment in my service at the eye dispensary in the Polyclinic Hospital, New York, complaining of epiphora and occasionally a filling of the right conjunctival cul-de-sac with the regurgitated viscid secretion of a chronic catarrhal sac. No mucocele or active inflammatory process. The lacrymal passages had been probed and medicated for the past five or six years with no results. October 20, 1915, cocaine injected in the skin around the sac. Dr. J. E. Burns assisted. Bone found carious. Bandage applied. After three months there was no secretion or epiphora.

Case XII.—An Englishwoman, aged thirty-six, who complained of pain over the left sac area with epiphora and secretion applied for treatment in my service at the eye dispensary in the Polyclinic Hospital, New York. Her eye was closed from the swelling in this region. Skin tense. She had been treated for attacks of this character for the past six or seven years with probes and medication. December 15, 1915, ether given. Dr. L. B. Nicholson assisted. The sac was a mass of frog spawn-like granulation tissue. Bone carious. Bandage applied. The area appeared normal in one week. The end of a month epiphora less than originally. After three months there was no epiphora.

Case XIII.—Englishwoman, employed in the laundry of the Polyclinic Hospital, had been probed and medicated for the past two or three years. She had an attack of a recurring phlegmonous kind. Skin swollen, red and tense over the right sac extending to lid and closing the eye. She applied for treatment in my service at the eye dispensary in the Polyclinic Hospital. December 17, 1915, cocaine injected into the skin. Dr. W. A. Ryan assisted. The corium above the sac was greatly thickened and contained a few pus cavities that were broken down and curetted from within. A great deal of roe-like granulation tissue was scraped away. The bone was carious. Bandage applied. No redness of skin at the end of one month. At the end of three months tissues quiet and some epiphora, but much less than originally. After four months epiphora not annoying indoors and only slightly in the wind.

Case XIV.—B. R., an American boy, aged eleven years. An attempt at removal of the right lacrymal sac through an incision in the skin was made about one year before by another surgeon. There was a broad scar remaining and the mucoid secretion regurgitated into the conjunctival cul-de-sac at intervals. On pressure over the sac area a great deal of thick viscid secretion filled the conjunctival cul-de-sac. He applied for treatment in my service at the eye dispensary in the Polyclinic Hospital, New York. March 22, 1916, ether was given. Dr. A. L. Bass assisted. Bone found carious. Bandage applied. At the end of four weeks there was no epiphora and the boy was well.

17 East Thirty-eighth Street

THE CONTROL OF THE NEXT EPIDEMIC OF INFANTILE PARALYSIS.

By F. ROBBINS, M.D.,

NEW YORK.

Since the first extensive epidemic of infantile paralysis in the United States (132 cases, Vermont) in 1894, and especially since the severe New York City epidemic of 1907, with approximately 2,500 cases, the control of this disease has become an urgent municipal problem. Nearly 9,000 cases were registered in the United States in 1910. The total figure for the current New York epidemic to date (August 15, 1916) exceeds 6,000 cases.

The great lesson taught by the last epidemic is the interpretation of anterior poliomyelitis as a contagious disease which spreads from one human being to another. Prophylaxis accordingly assumes greater importance in the control of future epidemics than ever before, and preparedness is now in order against the next invasion of the ultramicroscopic pathogenic agent. While the significance of the passive human carrier is beginning to be appreciated, the defensive measures in use fail to do justice to this source of contamination. As in practically all epidemic diseases, the actual original focus of infection and the starting point for all later cases of the disease must be sought in an infected human being. Patients in future will be strictly isolated and a better knowledge of the biological properties of the pathogenic agent will furnish a more reliable basis for the hygienic measures to be adopted in the community. The spread of poliomyelitis, in future epidemics, will be checked in a similar way as is now in use for infectious diseases, such as scarlet fever and diphtheria. Measures will be instituted for the removal and disinfection of the patient's secretions (from the respiratory no less than from the digestive tract), and for the purification of the sick room after his recovery. Healthy children in a stricken family will be regarded as potential germ carriers, and excluded not only from schools, libraries, and places of amusement, but also from street cars and other public conveyances. Visitors, children or adults will not be allowed in the homes of patients having the disease. The greatest difficulty will be encountered in restricting the social relations of adult members of infected families who, like children, may be passive germ carriers, although this fact is often disputed for commercial reasons. In this connection it will be found that the poliomyelitis germ is not ubiquitous, that is to say, it does not occur irregularly, in healthy individuals, but the bacilli carriers always come from infected surroundings.

The infection is now generally conceded to take place essentially through the invasion of the nasopharynx in which the virus of the disease has been known to persist for years. By means of experimental inoculation of nasal mucus into monkeys, it has been conclusively established that the infectious virus remains viable in the nasal passages for at least six months, in patients who have recovered from the disease, or in healthy persons from their surroundings. Typical poliomyelitis was transferred to healthy monkeys, by Osgood and Lucas, through the filtrate of the nasopharyngeal mucosa of two monkeys which had died, in the absence of any other demonstrable

infection, six weeks and five and a half months respectively, after the acute stage of poliomyelitis. Such observations illustrate the persistence of viable infectious poliomyelitis virus in the monkey's nasopharyngeal mucosa for weeks and months after the end of the acute paralytic stage and for a much longer time than its survival in the central nervous system. The fact cannot be overemphasized that the virus of this disease may exist for a very long time in an efficient condition, in the mucosa of the nasopharynx. On the basis of this assumption each cured case represents for a long time a serious source of danger to the community.

When the same conclusions are reached by a process of reasoning from different premises, the chances of the accuracy of these deductions are greatly augmented. With special reference to the poliomyelitis problem the importance of the nasopharynx as the entrance avenue of this infection and the urgent necessity of prophylaxis by nasopharyngeal hygiene have been pointed out for years by representative otorhinologists and public health experts in the persons of Dr. William Sohier Bryant and Dr. Charles E. North, whose teachings and recommendations, had they been generally understood and heeded, would in all human probability have checked the spread of the current epidemic, as they will presumably serve for the control of the next. The bacteriological laboratory can only provide the key and fit it into the recalcitrant lock of disease; the key must be turned, the door thrown open, and the light let in by the experienced clinician, the learned specialist, and the rare expert in preventive medicine.

The localization of the infectious virus in the nasopharynx fortunately renders it accessible to judicious intervention. No purposeful efforts have been made so far to control the infection which emanates from the nasal secretion, and it is perhaps too early in the century to anticipate the banishment of the pocket handkerchief at the appearance of the disease. The day will come when the customary cotton rag is replaced by the cheap and clean Japanese paper napkin, which is burned after it has been used. People will realize that for a long time after the patient's recovery his pocket handkerchief continues to represent a possible source of infection. Infants and children are helpless against the rubbing of strange handkerchiefs over their perspiring or grimy faces. The public roller towel of the past was innocuous as compared to the family pocket handkerchief. Bitter experience will drive home the lesson that neglected noses, mouths, and throats, are largely if not exclusively responsible for the ultimate crippling of the unfortunate victims of disease and ignorance.

The possible involvement of the hypophysis or pituitary body, by way of nasopharyngeal infection, in infantile paralysis (W. S. Bryant) opens up an entirely new vista and the existence of a pharyngeal hypophysis, an outpost of the cerebral hypophysis, adds to the force of the argument. Not only has the hypophysis been credited with a protective influence, in the sense of regulating the resistance of the body against disease, but the functional activity of all organs is influenced by the posterior portion of the cerebral hypophysis through the intermediary of the subsidiary centers located in the bulb and spinal cord. The posterior pituitary body is the chief center of the spinal system (Sajous). Before the outbreak of the next epidemic of anterior poliomyelitis, pathologists will have examined under the microscope the changes of the cerebral hypophysis of children who have succumbed to the disease. Reports will be available showing if the pharyngeal hypophysis, which is usually present, has undergone the compensatory hypertrophy sometimes noted in cases of organic pituitary disease, or if it presents inflammatory changes indicative of a local infection. The existence of close physiological and pathological relations between the nasopharynx and the hypophysis was pointed out by Citelli in 1912. Stimulation of the accessible pharyngeal hypophysis, with the object of furthering the function of the cerebral hypophysis through local application of radium, would seem to be at least worthy of a trial.

In diphtheria, a disease likewise contracted by nasopharyngeal infection, the changes of the cerebral hypophysis have been investigated and the cellular exhaustion which exists in these cases has been referred to the augmented compensatory activity of the hypophysis, as the result of the missing function of the medullary substance of the suprarenals (Abramow). The hypotonia of the vascular system in diphtheria is explained by Creutzfeldt and Koch as the result of degenerative changes of the intermediate lobe of the hypophysis, the part which secretes the blood-pressure raising substances. The clinical administration of pituitrin in diphtheria is followed by a distinct rise in blood pressure and combined pituitrin adrenalin treatment was recommended by Creutzfeldt and Koch as the most rational method of correcting the circulatory disturbance in diphtheria. The beneficial effects of adrenalin have been known for years, but although the interrelation of the endocrinic system is a part of contemporaneous knowledge, a more liberal application of the endocrinic principle is left to coming clinicians. The phenomena following upon the administration of pituitary substance are known to resemble those elicited by adrenal preparations. Unfortunately, no observations are available concerning the effect of hypophysis extract in cases of infantile paralysis, although many are claimed to have been benefited by adrenalin, and although it has been shown that the points of attack of adrenalin are sensitized by the simultaneous action of doses of hypophysis extract almost inert in themselves. The cooperation of these two substances causes a disproportionately stronger vascular contraction and the blood-pressure raising effect of adrenalin is also remarkably increased by the addition of small amounts of hypophysis extract. The rise of blood pressure is sustained much longer by pituitary substance than by adrenalin, and according to Sajous the temperature and the muscular tone are also apparently sustained for a longer time by the active principle of the hypophysis. A great practical advantage, as compared to adrenalin, especially in children having anterior poliomyelitis, consists in its simple administration by the mouth, without loss or impairment of therapeutic efficiency.

Serotherapy of anterior poliomyelitis has been recommended by Netter, in France, since 1910, on the basis of favorable clinical experience with the application to this disease of an efficient medication in cerebrospinal meningitis. The intraspinal injection of blood serum derived from patients

who have had infantile paralysis aims at bringing the virulent invaders of the nervous centers in contact with a fluid containing antibodies capable of neutralizing their pathogenic effects. It is not surprising that on etiological and other grounds the treatment of poliomyelitis with intraspinal injections of blood serum from convalescents has given rise to much controversy and adverse criticism. The method is now being tried in some hospitals in a limited number of cases, but it is too early to foretell the results of this tentative therapy.

In view of the appalling cost of a poliomyelitis epidemic—aside from the municipal expenses directly incidental to its prevalence, it is also necessary to count the financial encumberment of individuals, families, and ultimately the State itself, by the more or less crippled survivors—the question arises if the future will not see the wisdom of entrusting the welfare of the community to a competent guardian of the public health, who in his person unites the variegated but inert knowledge of bacteriologists, neurologists, practitioners, commissioners, etc., and whose competence in dealing with an incipient local epidemic is based on a thorough knowledge of the laws of universal epidemiology.

41 WEST FORTY-FIFTH STREET.

EPIDEMIC POLIOMYELITIS.

PRELIMINARY REPORT ON 33 CASES.

BY HERMAN B. SHEFFIELD, M.D.,
NEW YORK.

ALL but one of the cases were observed by me through the kindness of colleagues in the boroughs of Kings, Richmond, Queens, Manhattan, and the Bronx, and in Perth Amboy, N. J. Three of the patients were from 1 to 2 years old; fifteen from 2 to 3 years; nine from 5 to 6 years, and six from 8 to 10 years old. Twenty-two were boys and eleven girls. All of them were apparently in good health previous to the attack and well developed mentally as well as physically. The onset was very sudden in twenty-nine of the cases, while four of them showed signs of general malaise for from five to ten days. The history of infection could not be traced with any degree of certainty. In all but four of the cases poliomyelitis prevailed in the immediate neighborhood. In one case, a physician's child, there was a history of the father having taken his child in his automobile while attending to two cases of infantile paralysis. The presumption is also that while leaving his child in the car in front of the patient's house, it must have come in contact with some infected children of the neighborhood. In the cases of two children of Manhattan there was the presumption that the father in one case, an uncle in the other, both insurance collectors in the infected districts of Brooklyn, have conveyed the disease to the victims. One patient of Long Island had not come in contact with any child for six weeks previous to being stricken with the disease. Here also it was assumed that an adult carried the infection.

In nine cases one or more extremities were involved; in twelve cases the disease was limited to the muscles of the neck, throat, and palate, and in the remaining twelve the muscles of the chest, spine (patients were unable to turn around), and abdomen were affected. Nine children died, six of them within from 24 to 48 hours after the onset. The other children have greatly improved, whether fully or not it is too early to tell. The majority of cases began with headache and sore throat, the tonsils presenting either simple congestion or also small grayish white deposits. It was often associated with difficult, though not painful, deglutition. In the twelve cases in which the throat muscles were involved there was distinct hoarseness, the voice in speaking often resembling that observed after intubation. Associated with these symptoms was usually also regurgitation of fluids through the nose in drinking, so that the entire clinical picture fully agreed with that of postdiphtheritic paralysis; indeed, so much so that on five occasions the family physicians deemed it imperative to administer diphtheria antitoxin, in one instance as much as 18,000 units. In practically all the cases there was distinct drowsiness. The children, however, when aroused were perfectly conscious and able to respond to questions intelligently. Twitching of the muscles was very common even in the absence of high fever. In three cases convulsions of short duration occurred during the onset. The temperatures ranged between 100° and 104° F., most commonly about 102° F., while the pulse rate was invariably high, between 120 and 180 per minute, even in the absence of fever. Careful testing of the reflexes showed exaggeration in twelve cases, diminution in fourteen, and abolition in seven, the last being in the cases in which paralysis of the extremities predominated. In three children there was partial implication of the sphincters, in one of the anus, and two of the bladder, herein not being included the several cases of anuria of from twelve to thirty-six hours' duration. Muscular pain was pronounced some time during the course of the disease, most commonly at the onset, and I believe it was the pain which was responsible for the apparent presence of the Brudzinski and Kernig signs. Although the child was able to hold the head erect and to bend it backward, there was considerable difficulty or even inability to bring the chin down upon the sternum. The gastrointestinal tract was but little affected, about half of the cases gave a history of occasional vomiting, and the great majority of the children refused to eat on account of the difficulty in swallowing. On the other hand, some children maintained a very healthy appetite

for food, in fact, better than during good health, so much so that their parents cast some doubt upon the correctness of our diagnosis. In three cases slight facial paralysis was manifested and persisted after partial disappearance of the other symptoms.

Evidently the symptomatology of the disease during the present epidemic does not materially differ from that observed on previous occasions. In all epidemics certain groups of symptoms, depending upon the seat of the lesion, seem to predominate, and in the beginning tend to obscure somewhat the diagnosis; but with an epidemic prevailing, there should be no difficulty in arriving at correct conclusions. In this epidemic, as in previous ones,* we occasionally meet with atypical cases, as, for example, facial paralysis with crossed paralysis of the extremities, but these cases can readily be differentiated from encephalitis by the absence of spasticity and athetosis in the former and the fact that in poliomyelitis the spinal fluid shows an increase in albumin and globulin, a fair reduction of Fehling's, and a cellular increase, usually of mononuclears. This test, by the way, is of inestimable importance in all doubtful cases, when the question arises between poliomyelitis, rheumatic affection, acute scurvy, hip-joint disease, or injuries, and the like. Diphtheria can readily be distinguished from poliomyelitis involving the throat by the presence of Klebs-Loeffler bacilli in the former, and by the other clinical symptoms associated with diphtheria.

Exempting the six cases that succumbed to the attacks before any therapeutic measures had been employed (indeed two of them died during my consultation with the family physicians), I believe the results of the treatment presently to be outlined compare favorably with those of all other methods of treatment in vogue, including the injection of serum and adrenalin.

The treatment consists of cupping (six to ten cups on each side of the spinal column); hot (101° to 105° F.) mustard baths every four to six hours; sodium or ammonium salicylate (one or two grains for every year of the child's age, every two to six hours), and strychnine (small doses) internally; occasionally lumbar puncture, especially where twitching or rigidity is pronounced, and camphorated oil hypodermically, whenever respiratory difficulty presents itself. Immobilization of the paralyzed limbs, and light massage and passive motion are resorted to immediately, irrespective of acuteness of symptoms.

THE RICE DIET:

HOW TO PREPARE AND EAT IT.

By H. S. BARTHOLOMEW, M.D.,
NEW YORK.
PHYSICIAN TO THE CLINIC AT ROOSEVELT HOSPITAL FOR DISEASES OF THE STOMACH AND INTESTINES.

It is not the intent of the writer of this brief article to enter into the subject of diet or to extol the merits and uses of the so-called "rice diet," but to emphasize the importance of impressing upon the patient strict observance of details in the preparation and consumption of the rice if good results are to be obtained from the same. To tell the patient he must go on a rice diet for a stated length of time will not suffice; he must be impressed with the importance of the details laid down regarding it, otherwise it will fail of its purpose.

The so-called rice diet consists of *rice*, *butter*, *bread*, *water* and *salt*. Absolutely nothing else is allowed in the way of food or drink. This is to be eaten three times a day at the regular meal time—enough may be taken to satisfy the hunger. It must be eaten very slowly, thoroughly masticated, and at least one half-hour should be consumed at each meal.

The rice is to be freshly prepared each time and eaten while hot, not allowed to stand and become cold and soggy. It must be eaten with a fork—not a spoon. Butter is the only other article of food to be eaten upon the rice and bread—no cream, milk, or sugar is allowed. Salt may be used to season to taste.

Ordinary white wheat bread, at least one day old, freely spread with butter is the only other food to be eaten with the rice. One or two ordinary slices may be taken at each meal.

Water not too cold may be taken with the meals in moderation—nothing else in the way of drink. The water *must not* be drunk or taken into the mouth during mastication, as it will interfere with the action of the saliva upon the rice and bread. It must be drunk while the mouth is empty. Between meals water should be drunk very freely; the mineral and spring waters may be taken.

Butter must be used rather freely both upon the rice and bread, at least one-fourth of a pound being taken daily.

Preparation: Place two quarts of water in a kettle or pot of twice or three times this capacity to avoid boiling over, add one-fourth teaspoonful of salt and allow to boil vigorously, sprinkle in slowly five tablespoonfuls of white rice* previously rinsed in cold water, this being the average amount for one person—more or less may be used. Allow to boil vigorously without stirring or covering the pot for thirty minutes (by the clock), drain in a cullender and set on the back of a hot stove for a few minutes to dry—not too long as it will become hard and tough. Serve on a hot plate, add a piece of butter the size of a small hen's egg and mix with two forks, lifting the rice from the bottom of the plate each time until the butter is all melted, coating each grain of rice. Salt to taste and eat at once with a fork.

Patients taking the rice diet who are inclined to constipation must see that daily evacuations of the bowels are obtained. Morning aperients taken on rising give the best results. Carlsbad salts (the artificial being equally as good as the imported), one to two teaspoonfuls dissolved in a glass full of hot water and drunk the first thing on rising in the morning are excellent, especially in the robust and fleshy. To vaoid the unpleasant effects experienced by some, such as nausea, a good plan is to rise on awaking in the morning, take the aperient and return to bed for a short time.

By adhering strictly to the above details in the preparation and consumption, the rice diet patients will be impressed with its importance; they will not tire of it; proper digestion is insured and results will be most gratifying to both physician and patient.

207 West Fifty-sixth Street.

*Atypical Poliomyelitis, Medical Record, March 23, 1912.

*Of late the brown or natural whole rice is being advocated by many physicians owing to the fact that the vitamine is found in its outer covering or husk. It may be used in the rice diet.

THE STANDARDIZATION OF CLINICAL METHODS.

IT has long been the dream of all workers in clinical pathology that some day there will exist a standardization in the methods used in the clinical laboratories so that reports, often couched in identical phraseology, might mean the same thing. Many workers, especially those in charge of the clinical laboratories of large hospitals, have expressed themselves vigorously toward the same end. The subject is brought again to mind by the almost simultaneous appearance of two small manuals of laboratory methods.[1] Both are good, but an examination of their contents will show certain differences that are far from being merely academic. They are naturally restricted to the presentation of the single method which has seemed best or most convenient to the author and for the most part are free of discussion of the significance of findings. The differences in the methods offered are often trivial but sometimes vital, so that an adherent of one book could hardly duplicate the results of an adherent of the other unless the different substances examined for were present in unmistakable quantities.

McJunkin, for instance, recommends the addition of kieselguhr to the urine in order to clear it before testing for albumin, ignoring the fact that this will absorb a certain amount of the albumin present. He is also an enthusiastic user of the McJunkin polychrome stain, which is quite natural. Hill advises that the blood-acid mixture in the use of the Sahli hemoglobinometer be allowed to stand one minute before diluting, while McJunkin does not mention time at all, and both fail to speak of the importance of the direction of the source of light in the use of the Tallqvist scale. So it would be possible to point out several places where the two authors differ in quite essential details as to method. If one were to go further and include in such a comparative study others of the numerous manuals on the market the result would be exceedingly confusing to any except a trained clinical pathologist.

So much for the state of things as it exists at the present time. The advantages of a manual of standard methods would be many and, for the most part, obvious. Much of the laboratory work that is reported from hospital wards is done by the interne staff, which is composed of men who have had but little training and who apply various methods in what is only too often a casual fashion. A standardization of methods would at least introduce a uniformity of technique and reporting vocabulary and would help tremendously in enabling one to compare the reports from different institutions. If the reader is not convinced of the necessity of such a manual let him offer a specimen of sediment from a urine containing an increased number of leucocytes to a number of internes and ask them whether there is pus present. His conviction will be assured if he asks them to examine it daily for several days. The replies will vary to such an extent that it will be difficult to believe that all the men were examining the same specimen. Such a manual would have, of course, no place in the teaching at the medical school except that such and such a method would be noted as "the standard method" and the reasons given therefore. Each professor would teach as he saw fit and, in the hospitals also, special methods would be introduced as necessary or desirable.

No single man is capable of devising such a manual. It should be taken up by some national society or by a congress of the hospital clinical pathologists. It should include but one method for each test and should describe the technique in minute detail so that there could be no possibility of misunderstanding it. It should also prescribe the terms in which reports are to be worded. It should be as extensive or as limited in its scope as the circumstances at the time seemed to warrant, and above all it should be subject to fairly frequent revision so as to include improvements and changes as they might occur. The resulting manual would in many ways compare to the Pharmacopeia as an accepted standard, and the delegates should pledge themselves to the observance of its directions, each in his own institution. It would be a large job—there is no doubt about that—and the first edition would be long in preparing. Revisions would not demand so much time and the work would be distinctly worth while. That the accomplishment of this work would demand a considerable self-sacrifice on the part of the delegates as to both time and beliefs in favorite methods should only stimulate them to increased efforts to produce a creditable result. The MEDICAL RECORD hopes that the matter will be considered in the near future by some influential society and thereafter pushed through to a successful conclusion.

CONTRIBUTIONS TO NEGRO PSYCHOLOGY.

WE in America have here a psychological problem peculiarly our own. It is a matter of grave responsibility in whatever aspect it is presented to consideration. The psychopathologist is awaking to the importance of our negro population in his field of interest whether in practice or in scientific investigation.

Psychopathology is only one side of psychology,

[1] "A Manual of Practical Laboratory Diagnosis." By Lewis Webb Hill, M.D., Graduate Assistant, Children's Hospital, Boston. W. M. Leonard, Boston. 1916.
"Hospital Laboratory Methods," for Students, Technicians and Clinicians. By Frank A. McJunkin, A.M., M.D., Professor of Pathology, Marquette University School of Medicine, Milwaukee, Wis. Price $1.25 net. Philadelphia. P. Blakiston's Son & Co. 1916.

one mode of its application, and both stand in the service of society. Therefore Ferguson's* recently published report of his experimental study of the negro must arouse a practical medical and sociological interest because of the close relation and interdependence between mental capacity and social and individual health and efficiency. Ferguson summarizes the conclusions that have been drawn in the past concerning the mental and cerebral conditions of the American negro, some based on experimental studies, others not. There is wide difference of opinion in regard to the mental capacity of the negro as compared with that of the white, taking into account variously the size of the head, its contour, and the extent of convolution in the brain. Earlier studies were not very accurate, and the conclusions were untrustworthy. Later more accurate mental tests were made. Experiments of this sort, the Ebbinghaus completion test, the Columbia maze test, and others, were utilized by Ferguson to determine if possible the mental difference between the negro and the white, as well as between the pure negro and the mulatto.

The general results arrived at through experiments carefully made seem to prove a somewhat greater mental capacity in the white race and also in the mixed race compared with the pure negro. Valuable, however, as this study is, and the author does not claim for it more than a beginning of investigation into this difficult subject, psychopathology seeks a great deal more. The author of the monograph touches upon the further psychic factors, and without a due consideration of them there is the danger that always attaches to these static psychological tests, that of forgetting the broader psychic setting which keeps before us the intensively and extensively human character of the problem.

Some studies sent out from the Government Hospital for the Insane in Washington present the same racial differences from another point of view, and suggest, besides the social value in understanding the situation, the equally valuable contribution of negro psychology to the understanding and control of mental symptoms. This, of course, lays stress upon the genetic attitude toward the question, and that informs this valuable scientific study of Ferguson with fresh vitality. A genetic approach is essentially an interpretative one. It throws an illumination upon the differences which must exist in the physical cerebral capacity as well as the differences in psychical development, the over-emphasis in the American negro upon certain levels which we have come to know as infantile, either racial or individual. Moreover, interpreting them, it offers the broader basis for educational adjustment which Ferguson suggests. It makes us also more patient with this alien race. Dr. Evarts (*Psychoanalytic Review*, Vol. I, pp. 389-394) reminds us not only of their recent savage origin but of the unexampled position into which they were thrust, suddenly dropped into a civilization ages beyond them, to which, however, they were compelled to adapt themselves, with even the support of servile dependence early removed from them. Their adjustments have not come about by natural evolution. No wonder, then, that certain psychological reactions seem unaccountably in advance of cerebral development and that also an infantile or primitive psychical nature is uppermost. They have of necessity and with commendable success adopted much from their environment. Genetically, however, their development has not kept pace. Then comes also the admixture of white blood and, as Ferguson reports, the superiority of the partially white to the pure negro, which testifies to the hereditary development of brain capacity.

These two sides of the study, on the conscious and on the unconscious level, we might say, manifest in different ways the same attempt and partial success toward the adaptation required of this race placed in this anomalous situation. The latter study is essentially pathological, but as such is no less valuable in its contribution to an appreciation of the situation and most effective means in the accomplishment of this peculiar problem of adjustment. These psychoanalytic studies reveal the failure in adjustments and the compensations adopted, but as such they throw much light upon the fundamental elements of just such failure and mode of compensation in the psychoses and psychoneuroses of white patients of a higher grade of culture, but who, we must remember, are products of the same origins and whose unconscious inheritance therefore differs only in its greater accumulation and in the greater remoteness of the primitive elements.

*"The Psychology of the Negro," by George Oscar Ferguson, Jr., *Archives of Philosophy*, No. 36, April, 1916.

THE APERIOSTEAL STUMP AND ITS CARE.

UNDER this title H. H. M. Lyle (*Annals of Surgery*, June, 1916) makes some very interesting and practical suggestions. To obtain a useful stump three cardinal points must be observed: (1) Correct treatment of the bone; (2) correct treatment of the soft parts; and (3) prevention of stump atrophy. All amputations of the lower extremity should yield stumps capable of directly supporting the whole weight of the body. There are four methods of treating the bone: the osteoplastic, tendinoplastic, periosteal, and aperiosteal. Lyle says that the osteoplastic is the ideal method but requires ideal conditions; the tendinoplastic is of limited usefulness; the periosteal, although employed by the majority of surgeons in this country, is inferior to the other methods and should be abandoned; while the aperiosteal, in the advent of complications in healing, is the only one likely to furnish a useful end-bearing stump. He considers it the simplest, most universally applicable, and most practical.

After directing attention to the fact that when one examines standard artificial limbs for thigh amputations one will see that the stump socket is designed to avoid direct pressure on the end of the stump and to transfer as much weight as possible to the pelvic girdle, Lyle refers to a paper read at the meeting of the American Medical Association two years ago in which he called attention to the notoriously bad results obtained in amputation through the shaft of the femur and strongly advocated the employment of the aperiosteal method

where the osteoplastic could not be used. In a series of 47 femur cases from all parts of the country which he had occasion to examine he found but two true end-bearing stumps. In the majority of these cases he felt that the fault did not lie with the technique of the operator, but with the method of bone treatment and the after-care of the stump. The aperiosteal method aims to produce a painless supporting stump capable of early functional use. The technique of the bone section is as follows: Bone and periosteum are divided together, then a small cuff of periosteum 0.5 cm. in depth is removed and the marrow cavity is spooned out for a like distance. The cuff should not be dissected up as a preliminary step to bone section. In the removal of the cuff of periosteum no periosteal shreds should be allowed to remain; for such shreds, retaining their primitive osteogenetic function, are capable of producing painful bony spicules which would interfere with the early functional use of the stump. More than 1 cm. of periosteum and marrow should never be removed because of the possibility of resulting bone necrosis.

In spite of correct technique in the amputation itself the stump may become atrophied and useless if not quickly used as a real support. Lyle specifically states that this is the special feature of the aperiosteal method that he wishes to emphasize. His plan of after-treatment is as follows: "The patient is put to bed with the leg elevated. As soon as the wound is healed begin Hirsch's medico-mechanical treatment. Massage the stump twice daily, and after each treatment rub in a 2 per cent. solution of salicylic acid in olive oil. At night bathe in a warm sodium carbonate solution. Protect the stump with lamb's wool. Place a box at the foot of the bed and have the patient press the stump against it for from five to ten minutes three times a day, then four times a day, and finally every hour.

After each treatment energetically flex and extend the hip and knee. Now begin standing exercises. Rest the stump on a bran-bag or a cane-seated chair, at first placing the weight evenly on both legs; later place all the weight on the stump. At the end of two weeks the patient should be able to wear a peg-leg, later a permanent prosthetic appliance which directly receives the weight through the end of the stump."

Lyle believes that no surgeon should undertake an amputation by the aperiosteal or any other method unless he is willing to carry out the after-treatment which aims to provide a painless end-bearing stump. He also believes that an early functional use of the stump is the best method of preventing atrophy, although this is in direct opposition to the usually accepted teachings.

If Lyle's conclusions are generally approved by those who have had a similar opportunity to study conditions here and at the base hospitals abroad, it will mean a revolution in the technique of amputations of the lower extremity and in the manufacture of prosthetic apparatus designed to receive stumps formed in accordance with the principles which he has laid down.

RADIUM IN THE TREATMENT OF EXOPHTHALMIC GOITER.

Among the ever increasing number of morbid states in which radium is used externally or internally with more or less success, exophthalmic goiter deserves mention. Dr. W. B. Aikins of Toronto chose this as the subject of his presidential address at the meeting of the Ontario Medical Association, June 2, 1916, in which he pointed out that clinical experience showed that many cases did not respond satisfactorily to other methods of treatment, and that in many of these refractory cases he had found the employment of radium to be of decided benefit.

Abbe of New York was the first to use radium successfully in the treatment of exophthalmic goiter, and his favorable experience with this remedy had been repeatedly confirmed by other writers. The experiments of Victor Horsley and Finzi showed that the most constant changes after the application of radium affected the blood and lymph vessels. Aikins' own clinical experience showed that when applied over the thyroid the more penetrating radium rays diminished the vascularity and reduced the secretion of the gland.

Dawson Turner, who has had very favorable results, thinks that radium has two definite advantages as compared with the *x*-rays, namely, (1) The possibility of giving definite doses; (2) The fact that it can be applied without noise or excitement while the patient remains quietly in bed. Aikins reports at some length a number of cases of exophthalmic goiter in the treatment of which he had employed radium with excellent results.

The concluding portion of Aikins' presidential address is devoted to a brief consideration of the psychological aspect of the condition, and its significance in relation to treatment. But while he allows that in relief of those nervous symptoms, which form a prominent feature of exophthalmic goiter, psychotherapy plays an important rôle, he is of the opinion that physicians who have not had much experience of neurotic and neurasthenic people, and consequently do not understand them and have no sympathy with them, should refrain from undertaking medical treatment of this kind in which the psychic element is such an important feature.

ALCOHOLISM IN SWITZERLAND.

Switzerland, so far as we know, has never acquired the reputation of an alcohol-ridden land. We do not hear much about Swiss pauperism, crime, and insanity, nor of Swiss plans for fighting the drink evil. Nevertheless, at a meeting of the Zurich Medical Society last spring (*Correspondenz-Blatt für Schweizer Aerzte*, June 24) Dr. Meyer frankly asserted that Switzerland does not really deserve its good reputation as a moderation country. There is at present an alcohol monopoly in Switzerland which it is proposed to extend to the activities of household stills which have hitherto been exempt. A beer tax is also regarded as a future certainty, so that the consumption of spirits is not only bound to increase, but the government will evidently profit

in a twofold manner by such increase. Meyer does not state how the domestic output is to be incorporated into the State monopoly.

In this connection certain facts are of interest. In all the Swiss towns there are numerous little "joints" which depend entirely for their existence on the amount of spirits which they can sell before the men go to work in the morning. These places open at an early hour, and the quantity of spirits sold during this period is said to be immense. In rural districts brandy is served at table and is drunk not only by the women, but, so the author states, by the children as well. The peasant sells some of his home-made brandy, but reserves much for home consumption. The amount of alcohol sold by the State represents an expenditure per capita per annum of six francs, or about twenty-four francs per adult man. It is estimated that, if the home-made brandy consumption is included, this rate will be about doubled, or nearly fifty francs worth of alcohol for each grown man. The physician often sees cases of alcohol abuse and the best way of reaching the evil seems to be to restrict the home production in the interest of public health. It is certainly significant that while the great fighting countries are striving to cut down the manufacture and consumption of alcoholics, an isolated neutral country shows no disposition to follow this lead and even leans in the opposite direction.

Antityphus Sanitation in Mexico.

For those who know the condition of anarchy that prevails in many parts of Mexico, though naturally much less in evidence in the capital city, it will come as a mild surprise to learn of the systematic and scientific efforts being made for the control of the form of typhus which prevails in that country. From the *Boletin del Consejo Superior de Salubridad* for March we learn that there is a special service for combating typhus in Mexico City and outside municipalities in which the disease occurs in endemic form. The medical inspectors pay visits to all public places in the municipalities—prisons, churches, shops, theaters, etc.—in addition to domiciliary visits undertaken principally to pronounce upon their sanitary condition. Typhus victims are interned and their premises fumigated. When the infection shows no falling off, as in certain quarters inhabited by the very poor, a second visitation is made. During the month many objects, chiefly pieces of bedding, were destroyed by fire—in the words of the report there was a total of 3,547 incinerations. Special efforts were directed to make the street cars safe for travelers, over 15,000 notably dirty people being turned back from the cars during the month. The number of theaters visited was forty-six, of which all but six were pronounced clean. Of the whole number thirty-eight had been disinfected. The number of dirty patrons turned back was 4,111. Overcrowding was prevented by discontinuing the sale of tickets. The number of churches visited was eighty-two, and it was necessary to turn back 773 filthy subjects, 1,022 who had brought food with them, 141 sick people, and 154 beggars. Barbers apply parasiticides after hair cuts and shaves. Over 800 subjects were freed from lice. Despite the vigor of the campaign nearly 2,000 new cases of typhus appeared during the statistical month.

A Murphy Button in a Strange Situation.

At a meeting of the Société des Chirurgiens de Paris, Le Bec (*Revue de Chirurgie*, February, 1916) showed a soldier who had a scrotal tumor with fistula. This tumor proved to be a Murphy button. The patient had no hernia and the inguinal rings were normal. Le Bec's explanation of the matter is that some surgeon had done a castration and for cosmetic reasons had wished to put something in the scrotum to take the place of the ablated testicle; and that he had taken for this purpose the first thing that came to hand. However, the button, often invaluable in its proper field, was intended by its originator to cut its way out and it had begun to run true to form in this instance.

News of the Week.

Poliomyelitis Epidemic Continues.—The total number of poliomyelitis cases in this city to August 17 was 6,658 and the total number of deaths 1,497. In the remainder of the State, up to the same date, 957 cases had occurred. The prevalence of the disease in the city as compared to other years is shown by the following figures prepared by the Health Department: In 1913, 310 cases; in 1914, 129 cases; in 1915, 92 cases; in 1916, up to August 5, 4,856 cases, and to August 12, 6,140 cases. In New Jersey also the disease continued to spread during the week, the total number of cases reported to August 12 being 1,461. In Pennsylvania 296 cases had been reported to the same date, 161 of them in Phialdelphia. The question of opening the New York City public schools on September 11 was discussed at a conference with the Health Commissioner recently, and as a result the Board of Education passed a resolution authorizing the president of the board to act upon any recommendation made by the Health Department. President Wilson recently signed an act appropriating $85,000 for use of the Public Health Service in preventing the spread of this disease, and $50,000 in addition to provide for the appointment of more assistant surgeons.

Clinics for Poliomyelitis.—Because of the success of the special poliomyelitis lecture clinics conducted recently under the auspices of the Department of Health and in response to numerous requests that they be repeated, a new course of clinics has been arranged through the cooperation of the attending physicians at the various hospitals where these cases are treated. Attendance at the clinics will be strictly limited, and physicians desiring to attend should apply in advance to the respective hospitals for cards of admission. Groups will be formed in the order of application. When the group is complete the applicant will be referred to the clinic held in the following week. Clinics will be held at Bellevue Hospital, Pavilion 32, every Monday at 4 P. M.; at Lebanon Hospital, every Tuesday at three thirty; at Willard Parker Hospital every Wednesday at four; at the Babies' Hospital every Thursday at four; at Mt. Sinai Hospital every Friday at four, and at the Kingston Avenue Hospital every Friday at four. The clinics will continue for the next five or six weeks.

Health of the Canal Zone.—The chief health officer of the Canal Zone reports that no cases of yellow fever, smallpox, or plague originated on or were brought to the isthmus during the month of June, 1916. In fact, the last case of smallpox on

the isthmus occurred in a passenger from a steamer arriving at Cristobal on February 3, 1915; the last case of smallpox contracted on the isthmus was in 1907. The last case of yellow fever contracted on the isthmus occurred in November, 1905, while the last case of bubonic plague contracted there dates back to August, 1905. During the month of June the health of the employees at the canal remained good, the total admissions to hospitals and quarters being 756, a rate of 287.99, as compared with 285.45 for the preceding month, and 369.87 for the corresponding month of last year. The total number of deaths from all causes among employees was 20, of which 17 were due to disease, giving a death rate of 6.48, which is higher than that for the same month of 1915. There were no cases of typhoid fever during the month. A census of the Canal Zone completed shows a total population of 31,048, including employees, non-employees, and military garrisons, within the Zone limits. The population of Panama City is now 60,778 and of Colon 24,693; during the month of June the death rate in the former was 30.01 and in the latter 24.30 per 1,000.

Army Medical Corps Examinations.—The Surgeon General of the United States Army announces that preliminary examinations for appointment of first lieutenants in the Army Medical Corps will be held on September 5, 1916, at points to be hereafter designated. Full information concerning these examinations can be procured upon application to the "Surgeon General, United States Army, Washington, D. C." The essential requirements are that the applicant shall be a citizen of the United States, between 22 and 32 years of age, a graduate of a recognized medical school, and of good moral character and habits, and shall have had at least one year's hospital training as an interne, after graduation. The examinations will be held simultaneously throughout the country at points where boards can be convened. Due consideration will be given to localities from which applications are received, in order to lessen traveling expenses as much as possible. In order to perfect all necessary arrangements for the examinations, applications should be forwarded at once to the Adjutant General of the Army. There are at present over two hundred vacancies in the Medical Corps of the Army.

Extra Milk Depots.—In response to the appeal of mothers in the Williamsburg and Brownsville districts of New York, Nathan Straus has promised to continue the maintenance of the emergency milk depots which were established in these districts early in the summer. The original purpose was to supply milk for the children of the locked-out garment workers, and this necessity having largely passed the closing of the depots was announced. The announcement, however, brought forth such urgent requests for the continuance of the charity that it was decided to keep the depots open for the present, and if the demand warrants it to make them permanent.

Exchanging Surgeons.—Drs. Hugo Zieschank and Otto Glantz, two German army surgeons, sailed from New York last week for Holland, en route for Germany, having been sent from Australia to be exchanged for two British surgeons now prisoners in Germany.

Death of Aged Indian.—Chief Givan-Ha-Day (Falling Snow), 104 years old, and said to have been the oldest Iroquois Indian, died in a hospital in Toledo, Ohio, on August 12. The chief had gone to Toledo a few days before to take part in a play given by the Boy Scouts, and succumbed to the infirmities of old age.

American Chemical Society.—A meeting of this society will be held in New York, in conjunction with the second national exposition of chemical industries, on September 25 to 30, 1916. Sessions will be held at Columbia University and at the College of Physicians and Surgeons, New York, as well as at the Grand Central Palace and at Rumford Hall in the Chemists' Club Building. A detailed program will be issued shortly by the secretary of the society.

Personals.—Dr. Albert Warren Ferris, formerly medical expert and director for the Commissions for the Reservation of Saratoga Springs, has gone into practice in that city. No physician is any longer connected with the State control of the springs and bath houses.

Dr. Charlton Wallace of New York announces his removal to 11 East Forty-eighth Street.

Dr. Isham G. Harris, formerly medical superintendent of the Mohansic State Hospital, Yorktown, N. Y., has been appointed superintendent of the Brooklyn State Hospital, succeeding Dr. Elbert Somers, who resigned on August 1.

Gen. William C. Gorgas, U.S.A., head of the Yellow Fever Commission of the International Health Board of the Rockefeller Foundation, arrived at Bogata, Colombia, from Panama, on August 9. General Gorgas will consult with the Colombian government on sanitary conditions of ports in that country.

Glanders Diminishing.—The Department of Health of New York City reports that the success of the administrative measures for the control of glanders among horses during the past year is shown by the decrease in the number of cases observed. These measures embrace the sanitary control of all stables in the city, the closing of public horse troughs, the making of specific tests on all horses exposed to infection and the destruction of all animals reacting, the supervision of horse-shoeing establishments, and the distribution of circulars containing information on the disease, among horse owners, stable keepers, etc. During the first quarter of 1914, 229 cases of glanders were reported, of 1915, 232 cases, and of 1916, 127 cases; during the second quarter of 1914, 313 cases, of 1915, 161 cases, and of 1916, 82 cases; during the third quarter of 1914, 227 cases, and of 1915, 145 cases; and during the last quarter of 1914, 384 cases, and of 1915, 166 cases. It will be noted that the reduction has been steadily progressive.

Obituary Notes.—Dr. EDWIN BASSETT TEFFT of New Rochelle, N. Y., a graduate of the University of Buffalo, medical department, in 1864, a member of the American Medical Association, the Medical Society of the State of New York, the Westchester County Medical Society, and the New Rochelle Medical Society, and consulting physician to the New Rochelle Hospital, died at his home, after a long illness, on August 6, aged 72 years.

Dr. GEORGE S. CRAWFORD of Clifty, Ind., a graduate of the Medical College of Indiana, Indianapolis, in 1874, and a member of the Indiana State Medical Association and the Decatur County Medical Society, died at his home on July 26, after a long illness.

Dr. MICHAEL KELLY of Fall River, Mass., a graduate of Bellevue Hospital Medical College, New York, in 1885, and a member of the Massachusetts

Medical Society and the Medical Society of Bristol County, died at his home, after a long illness, on July 28, aged 61 years.

Dr. JAMES HUDSON WHEELER of Pittsfield, Mass., a graduate of the Detroit Homeopathic Medical College, Detroit, Mich., in 1873, died, after a long illness, on July 25, aged 69 years.

Dr. JOSHUA S. WOOD of Irvinton, Ga., a graduate of the Atlanta Medical College, Atlanta, Ga., in 1877, died at his home, after a long illness, on July 20, aged 72 years.

Dr. ANDREW P. WILSON of Los Angeles, Cal., a graduate of the University of Southern California, College of Medicine, Los Angeles, in 1902, and a member of the American Medical Association, the Medical Society of the State of California and the Los Angeles County Medical Society, died suddenly on July 20, aged 50 years.

Dr. WILLIAM F. FAIRBANKS of Kansas City, Kan., a graduate of the Western Reserve University, School of Medicine, Cleveland, in 1886, and a member of the Kansas Medical Society and the Wyandotte County Medical Society, died at his home on July 22, aged 56 years.

Dr. LOUIS HORNBY FRASER of Presque Isle, Me., a graduate of the College of Physicians and Surgeons, Boston, in 1910, and a member of the Maine Medical Association and the Aroostook County Medical Society, died suddenly on July 23, aged 43 years.

Dr. ALVAH C. LEWIS of Salt Lake City, Utah, a graduate of Columbia University, College of Physicians and Surgeons, New York, in 1877, and a member of the Utah State Medical Association and the Salt Lake County Medical Society, died in San Diego, Cal., on July 12.

Obituary.

JOHN BENJAMIN MURPHY, M.Sc., M.D., LL.D.

CHICAGO.

Dr. JOHN B. MURPHY of Chicago, professor of the principles and practice of surgery in Northwestern University, died suddenly, from heart disease, at his summer home on Mackinac Island, Mich., on August 11. Dr. Murphy had been in poor health as a result of overwork during the winter, but was not thought to be dangerously ill; his condition was considered to be partly the result of his having been poisoned at the banquet given to Archbishop Mundelein at the University Club, Chicago, last winter.

Dr. Murphy was born in Appleton, Wis., on December 21, 1857, and was educated in the public grammar and high schools, afterward entering Rush Medical College, Chicago, from which he was graduated in 1879. After three years of general practice he went to Germany for study, and on his return he entered the field of clinical surgery in which he achieved great distinction, and to which he had contributed largely. In 1902 he was awarded the Laetare medal by Notre Dame University, a medal given each year to a Catholic layman who has done conspicuous service to humanity, science, art, or religion, and his work was recognized also by the University of Illinois which bestowed the degree of LL.D. on him in 1905, by the Catholic University of America, which gave him the same degree in 1915, and by the University of Sheffield, England, which in 1908 honored him with the degree of M.Sc. In addition to his work in the Northwestern University Medical School, Dr. Murphy was professor of clinical surgery in the Chicago Postgraduate Medical School, advisory surgeon of the Cook County Hospital and the Alexian Brothers' Hospital, chief surgeon at Mercy Hospital, and attending surgeon at the West Side Hospital. He was a member of the American Medical Association, of which he was president in 1911, the Illinois State Medical Society, the Cook County Medical Society, the American Association of Obstetricians and Gynecologists, the American Surgical Association, the Southern Surgical and Gynecological Association, the Western Surgical Association, the Chicago Orthopedic Society, the Chicago Surgical Society, the American College of Surgeons, and the Mississippi Valley Medical Association, an honorary member of the Royal College of Surgeons of England, and a life member of the Deutsche Gesellschaft für Chirurgie, and of the Société de Chirurgie of Paris.

Dr. Murphy, besides being gifted with an exceptional technical skill, was a man of striking originality, and he enriched medicine with many useful inventions; two of the most noted of these were the well-known "button" for intestinal anastomosis, and artificial pneumothorax, by the injection of nitrogen into the pleural cavity, for the compression and "splinting" of the tuberculous lung.

Correspondence.

A SUGGESTION IN THE PREVENTION OF INFANTILE PARALYSIS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—It seems well proven that infantile paralysis is an infectious and communicable disease, due to a specific virus which exists constantly in the central nervous organs and upon the mucous membrane of the nose, throat, and intestines in persons suffering from it. The virus enters the body by way of the nose and throat and is known to leave it in the secretions of these organs, and is distributed by sneezing and coughing and by articles contaminated with these secretions. In the interior of the body it is probably destroyed in a few days but persists in the mucous membrane of the nose and throat several weeks; it disappears from the nose and throat in humans, in most cases in four weeks, though it has been known to persist for a number of months. The virus has been found in the nasal secretions of healthy persons, who come in contact with the sick—therefore both the healthy carrier and the chronic carrier have to be reckoned with.

The fact that the virus has never been demonstrated in the blood of the sick discredits the idea that it can be spread by blood-sucking or biting insects. A period of six weeks is considered right for the length of quarantine. In the light of the brilliant work lately done on this disease by many eminent men, it is conspicuous that if the nasal secretions can be kept free from contamination with the harmful virus, then the spread will stop. This virus must contain an organism specific to the disease, though never yet definitely brought to light.

Isolating the cases early and care with the hands and secretions, together with quarantine sufficiently long, are our best weapons of defense. This is being done, but there will continue to be cases that escape notice. One may ask, can we render the mucous membrane resistant by the use of an antiseptic in the nose and throat that will destroy the virus or so lower its virulence that it cannot take hold?

An antiseptic possessing the power to destroy the virus and in no way injurious to the Schneiderian membrane should be given a trial. The one that seems most to possess this bactericidal power, and at the same time is nonirritating to the nasal mucous membrane, is a solution of colloidal silver. It clears the nasal mucosa of the persistent influenza bacillus better than anything I ever used. If every mother in infected districts would put into each nostril of her children twice a day one medicine dropper full of 10 per cent. colloidal silver solution for a period of six weeks, no harm would come from it but to the children's clothes—and who knows what good. The results might be brilliant, and this is here offered as a suggestion probably worthy of trial.

JOHN W. WINSTON, M.D.
THIRTY-THIRD STREET AND COLONIAL AVENUE,
NORFOLK, VA.

A PREVENTIVE AND CURE FOR POLIOMYELITIS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Last year I immunized a monkey with milk of magnesia (MgO_2H_2) against poliomyelitis by injecting the following into the peritoneal cavity and spine: Milk of magnesia 0.5 c.c., secretions from nose and throat 0.5 c.c., add sterilized distilled water 5 c.c.; this thins it enough to pass needle. Waiting ten or fifteen days after inoculation, no symptoms developed. The secretions from the nose and throat in poliomyelitis are acid. The blood and spinal fluid are subalkaline. The point of entrance lies in the nose and throat and the virus thence passes to the intestine. Now MgO_2H_2 increases alkalinity and when the virus comes in contact with it decomposition or neutralization is the result. As a preventive I have given milk of magnesia to over 150 children since July 3 living in infected districts and not one has contracted the disease. As the virus enters the nose and throat passing to the intestine, it can readily be seen how efficacious MgO_2H_2 is. Milk of magnesia is slowly soluble and mixes thoroughly with the virus, besides remaining in the mouth and intestine much longer than some more soluble hydroxide. Dosage: Children, 1 to 2 years, 15 to 20 drops; 3 to 4 years, ½ teaspoonful; 5 to 7 years, 1 teaspoonful; children older than 7 years, 1 to 2 teaspoonfuls, in water every four hours.

As a cure I would suggest a serum published by me in the *International Clinics*, Vol. IV, 24th Series, under "Treatment of Lobar Pneumonia." This serum can be used for any infectious disease. It produces active immunization by inducing leucocytosis and increasing the antibodies or defensive enzymes. It is prepared as follows: Dried horse serum from 500 c.c. of fluid serum; sodium carbonate (anhydrous), 1.62 grams; sterilized distilled water, 500 c.c. Dissolve the dried horse serum in water, then add the anhydrous Na_2CO_3. Dose: 30 c.c. to 100 c.c. introduced into the general circulation, either intravenously or hypodermically. This dosage for adults. Children in proportion to weight. Intraspinally 5 c.c. to 15 c.c., first withdrawing this quantity or a larger amount of spinal fluid. Often one dose cures a case of poliomyelitis. Leucocytosis and immunity take place and the subalkalinity is overcome. When the spinal fluid is normally alkaline the enzymes there are activated. The horse serum and Na_2Co_3 bring about this result.

BROOKLYN, N. Y.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

NERVE INJURIES IN WAR—NERVE SHOCK—FUNCTIONAL PARALYSIS—MODERN TESTING—TORN NERVES—HARVEIAN SOCIETY'S CLINICAL MEETING.

LONDON, July 22, 1916.

MAJOR C. F. BAILEY, R. A. M. C., has contributed a paper on Nerve Injuries in War Time to the Brighton Medico-Chirurgical Society. He opened with a warning against jumping at a conclusion, and emphasized the importance of careful search for sensory defects, particularly loss of epicritic sensibility, and then mentioned the fallacies that may arise and the difficulties experienced with foreigners, maligners, and patients of little intelligence. He considered condenser-testing of great value as superseding faradic and galvanic muscle-testing. To obtain extreme accuracy he tested doubtful muscles against normal ones on the opposite side. He referred also to the difficulty experienced in preventing the powerful currents necessary to cause contraction of damaged muscles, from overflowing and so setting up contraction in the opponents of the damaged ones, for that would be injurious instead of beneficial. At the Eastern General Hospital cases which had been operated on proved the accuracy of the diagnosis obtained by the condensors. Accounts of various cases of injured nerves were given, including hypoglossal, spinal accessory, third and fourth cervical, posterior thoracic, ulnar, median, musculo-spinal, sciatic, etc.

Major A. H. Buck, R. A. M. C., president, discussed cases of nerve-shock and asked whether in those in which the nerve is constricted, but not divided, paralysis is shown by complete reaction of degeneration and further if the trunk of the nerve is ruptured in its course does it recover function without operation?

Captain Gervis referred to the extreme accuracy of modern methods of testing and asked how the difference in skin resistance is allowed for. Lieut.-Col. Jowers asked abou the condition of nerves supposed to be functionally paralyzed.

Dr. E. R. Hunt reported a case of local anesthesia immediately following extraction of a tooth (lower molar), due, it may be presumed, to injury of the mental branch of the inferior dental nerve. Major Bailey (replying) said cicatricial constriction might produce complete reaction of degeneration. If this were complete, or even of high degree, it indicated exploration; if the nerve was found to be torn across, the ends might be so close that recovery was possible, though not probable and so was a negligible consideration. The difference of skin resistance was met by interposing such a large constant resistance that the variation in the skin could be neglected.

At the Harveian Society's clinical meeting the following cases were shown: (1) Septic papillomatosis of lower extremity, producing great over-overgrowth; (2) soft sore which had lasted thirteen years and led to extraordinarily extensive scarring; (3) intrathoracic tumor in a young woman, *x*-rays revealed a shadow behind the upper part of the sternum and the microscopical examination supported the view that it was lymphadenomatous; (4) multiple osteomata developing in an adult (male); (5) a man who had been operated on for tempero-sphenoidal abscess; (6) a patient with stone in ureter; an *x*-ray was shown with an opaque bougie

in the ureter alongside the stone; (7) woman with enlarged liver (jaundiced); (8) photograph of patient who survived three days after an electrical burn caused by a current of 11,000 volts which had destroyed three of this patient's limbs.

Mr. J. E. R. McDonagh, in his Hunterian Lectures (R. C. S.), mentioned some points as to the use of intramine and ventured to prophesy that this drug is going to play a very important part in the treatment of syphilis, and not only so, but in all chronic infections, since it has already been shown to be of considerable value in tuberculosis and in chronic gonorrhea. He even thinks it probable that it may find a place in the treatment of malignant disease.

Progress of Medical Science.

Boston Medical and Surgical Journal.

August 3, 1916.

1. Results Obtained in the Treatment of Diabetes Mellitus. May 1, 1915—May 1, 1916. Elliott P. Joslin.
2. Definition and Detection of Acidosis in Diabetes Mellitus. Albert A. Hornor.
3. Observations on the Blood Sugar in Diabetes Mellitus. Orville F. Rogers, Jr.
4. Tests of Renal Function from the Standpoint of the General Practitioner. Francis W. Peabody.
5. Eye Changes in Renal Diseases—Their Diagnostic and Prognostic Value. Peter Hunter Thompson.
6. The Physiological Point of View and Autopsies. Francis J. McCrudden.

1. Results Obtained in the Treatment of Diabetes Mellitus.—Elliott P. Joslin refers to two former communications on this subject in which there was a note of hopefulness unusual in an article on diabetes and presents the present communication because it seems to show that these new hopes and explanations of avoidable causes of death were justified. Speaking roughly, he says that the average duration of life of 408 of his fatal cases has been five years, and that of 490 of his living cases has already reached six years. During the year ending May 1, 1915, 211 cases of diabetes came under his observation and of this number 15 per cent. died; during the subsequent year 314 cases were seen and 11.7 per cent. of these have died. A conservative estimate would place the decrease in mortality over the previous year at 20 per cent. These figures become still more encouraging when the writer adds the study of thirty-seven fatal cases seen this last year which show that death might have been deferred in about one-half of these if the methods of treatment now in general use had been adopted. A comparison is also made of the duration of fatal cases of diabetes in Massachusetts for 1915, compared with the author's total fatal cases. This shows that the greatest difference in mortality between the statistics of the State and those of the writer lies in the early decades of life. A further startling difference lies in the number of cases in each group who succumbed during the first year to the disease. In the writer's series of 490 cases of diabetes, 94 per cent. have already passed the first year of the disease, the danger zone of the diabetic. In a study of the causes of death in 408 cases of the author's series it was found that two out of every three died of coma, that 87 per cent. of all those who succumbed during the first year of the disease died of coma, and that this was the case in 100 per cent. of fatal cases in children. Therefore, if the mortality of diabetes is to be reduced, our energies should be directed first toward the avoidance of coma, because the treatment of coma is so unsatisfactory; and, second, particular attention should be exercised in the management of cases of diabetes in the first year following the detection of the disease. Furthermore, all cases should be persistently followed up, and the good effects of treatment should not be allowed to lapse by indifference or neglect.

2. Definition and Detection of Acidosis in Diabetes Mellitus.—Albert A. Hornor observes that it is easy to note the drowsiness, exaggerated respiration, and dry skin, so characteristic of the diabetic about to die in coma. So seldom does the patient recover and so temporary are the few recoveries recorded that it is manifestly necessary for us to recognize precomatose conditions if we would save the diabetic patient. The author discusses the demonstrable differences between the metabolism of a comatose diabetic and the metabolism of a healthy individual, and says in conclusion tht the acidosis of diabetes mellitus, aside from its clinical picture of exaggerated respiration, drowsiness, and rapid pulse, may be defined as a condition in which the carbon dioxide tension in the blood, and consequently, in the alveolar air is reduced; the acetone bodies in the urine and blood are increased and associated with this is a rise in the excretion of ammonia; glycosuria is marked, and, saving exceptional cases, toward the end of prolonged coma, the carbohydrate balance is markedly negative. All these factors are important in determining the degree of acidosis, and, where time and facilities permit, should be ascertained. The detection of glycosuria, the demonstration of a positive ferric chloride reaction, and the determination of a diminution in the alveolar carbon dioxide tension, are the procedures suitable for beside use. The carbohydrate balance is also a valuable indication and one surely to be determined, but, unfortunately, it must always furnish information, in part, at least, a day late.

3. Observations on the Blood Sugar in Diabetes Mellitus.—Orville F. Rogers, Jr., aims to present some conclusions as to the value or necessity of determining the blood sugar in treating diabetics, either from a prognostic or a therapeutic standpoint. He states that diabetics have a higher blood sugar when they are excreting sugar in the urine than they do when the urine is rendered sugar-free. The threshold of sugar excretion varies in different diabetics and apparently in the same individual at different times. Sometimes the blood sugar returns to normal under treatment, and this is generally in the milder cases, though there are some exceptions to the rule. A persistently elevated blood sugar may be an indication of the greater severity of the disease or it may occur in apparently mild cases, but generally associated in the latter instances with some renal impairment. By keeping the carbohydrate intake well below the limit of tolerance, as shown by the appearance of glycosuria, it has been found that the blood sugar will almost, if not quite, sink to normal, and their experience leads to the belief that efficient treatment can be carried out in most instances, using the urinary sugar alone as the therapeutic guide. There are a certain number of severe cases with marked acidosis or nephritis in which the true picture of the condition is much illuminated by direct blood examination, both for sugar and alkali reserve.

6. The Physiological Point of View and Autopsies.—Francis H. McCrudden states that at the Robert B. Brigham Hospital they are demonstrating to physicians, students, patients, and others, the usefulness of the physiological point of view of the problem of treatment in chronic disease, and it is evident that the patients appreciate its usefulness. From the large proportion of cases of death in which permission for autopsy is obtained, it has become evident that their ideas are spreading to the relatives of the patients. Since the hospital opened on April 1, 1916, complete autopsies have been carried out in 70 per cent. of all

those dying. No other American hospital has attained results that at all approach these. While many factors may have contributed to this unusually high percentage of autopsies, in the last analysis success depends upon the degree to which the relatives can be made to appreciate what has been done to help the deceased and the extent to which they can be made to understand that in giving permission for a post mortem examination they may be contributing something toward helping other patients. The figures presented bring out another point, namely, that the emphasis laid on the physiological point of view need not lead to any neglect of pathological anatomy, since in this hospital the direct result has been an increase in the possibilities for pathological-anatomical studies.

1. **Shoes, Physiological and Therapeutic.**—Dexter D. Ashley emphasizes the fact that we should not try to combine all the qualities in a single shoe to meet all conditions, occupations, and positions in life. He says that in prescribing shoes the doctor's path will be smoother if he can modify the shoes commonly worn by the patient or, if these are impossible, direct him to select a fairly good trade shoe to be modified. Seldom is the custom shoe perfect or exactly as designed, and the patient will expect much more from a "made-to-order" shoe in the way of immediate relief of symptoms. Comparing the outline of the foot with the shoe of civilized man, ordinary shoes would appear as a monstrosity to us were it not that long association with these forms has dulled our perceptions. The physiological shoe for approximately normal strong feet should conform to the foot outline without undue restraint. The sole should be strong, elastic, straight to the floor line, with sufficient curve to prevent stubbing. It should be broad enough to carry the vamp, and may have a pointed or rounded toe. The center of the sole should correspond with the center of the foot. The welt should be wide enough to protect the vamp. The insole should be of flexible leather, and should be flat or very slightly convex in the anterior part behind the anterior metatarsal arch. The shank should be rather narrow, yielding, and elastic, tending to the outer side. The heel should be as wide as the individual's heel in a snug counter and ⅝ to 1 inch high for adults. It should be built straight down from the rand and set well forward, centering under the os calcis. Since most of us have become accustomed to unnatural positions of the feet, to place them at once in an approximately physiological position would arouse pain and discomfort by bringing into action unused muscles, ligaments, and weight-bearing facets. The writer points out in detail the defects of ordinary shoes, and shows skiagraphs of feet taken through the shoes which illustrate the mechanical disadvantages of faulty construction.

2. **Herpes Corneæ "Febrilis."**—Samuel Theobald writes with special reference to the etiology of this condition. He thinks that the qualifying term "febrilis" is not well chosen; for though herpes labialis and, perhaps more general, facial herpes not infrequently occur as an accompaniment of "colds," attended by fever, this is, according to his observation, not true of corneal herpes. He says further that the severe pain which some describe is not, in his experience, a usual symptom of this condition. He feels that the primary lesion which gives rise to simple herpetic keratitis, and which explains the corneal hyperesthesia, is situated in the ciliary ganglion, and shows why he thinks this view is tenable. In the treatment of herpetic keratitis the local remedies which he has found most useful are holocaine and atropine; frequently one, sometimes both, of these are supplemented by instillations of dionin. The rapid subsidence of the keratitis is seldom observed and the patient should be prepared for a somewhat tedious recovery.

3. **Management of the Complications of Pregnancy.**—John A. McGlinn discusses a number of complications of pregnancy with which he has had personal experience. In two instances in which pregnancy occurred in a retrodisplaced uterus the uterus became incarcerated. In both of these instances, it being impossible to replace the uterus manually, the abdomen was opened and the uterus freed from incarceration by internal manipulation. One of these patients miscarried, the other was delivered at term of a living child. In cases of this kind the author is opposed to both abortion and the rupture of the membranes unless laparotomy is positively contraindicated. He warns against attributing a right-sided abdominal pain to appendicitis in every case, since the infection of the right urinary tract is a more frequent cause of this pain than appendicitis. In discussing such complications as appendicitis, intestinal obstruction, and fibroid tumors of the uterus, one point which has impressed the writer is the frequency of postoperative abortion. Finally he protests against the tendency on the part of reputable physicians and surgeons to terminate early pregnancy because vomiting is aggravated, and says that as a matter of fact very few cases of toxenia of early pregrancy call for the termination of gestation. The majority of such cases are not toxic at all, and the condition is cured under proper treatment.

6. **The Nephritic Toxemia of Pregnancy.**—Arnold H. May points out that the growing uterus, variously weighted, depending on the development of the child, by pressing on the renal excretory apparatus, is a factor in the etiology of the nephritic toxemia of pregnancy, and advocates as a prophylactic measure in cases in which there is a predisposition to this condition, and as an adjuvant factor in the treatment where the disease already exists, the use of a special bed. This bed consists of a headpiece and a footpiece separated by an area of about 2 feet, each part having a separate spring and mattress. Between these parts the bed is open, except for an adjustable sling made either of rubber or cloth, preferably the former. The rubber sheet is sufficiently long so that it can be depressed to various degrees to accommodate the abdomen. The patient assumes the recumbent position with the face down. By this means a great degree of comfort may be assured the patient and pressure is withdrawn from the kidney.

7. **The Pathogenesis of Psoriasis.**—Abner H. Cook reports ten cases in which the skin condition was unquestionably psoriasis, all of whom were treated with emetine hydrochloride, and three recoveries resulted; these three patients had pyorrhea alveolaris with *Endameba buccalis*. One case of pyorrhea failed to respond to the three courses of emetine, and there was no improvement in his psoriasis. One patient had a seminal vesiculitis, and after eradicating the disease with autogenous vaccine and other appropriate measures the psoriasis cleared up. Fistula in ano, discharging pus,

was found in one case; after operation the fistula healed and a complete recovery from psoriasis resulted. The removal of infected tonsils was followed by the disappearance of the psoriasis in one case. Syphilis was the only infection found in one case, and iodides and mercury had no effect upon the psoriasis. Two patients having psoriasis but no other disease or infection were dismissed without relief. The cases of recovery from psoriasis, after the removal or cure of other infections, strongly suggest that these infections caused the disease. Further, on account of the character of the infections it is suggested that the organisms most likely causing psoriasis were the staphylococci and streptococci.

8. **Medical Women in History and Present-Day Practice.**—Mary Sutton Macy concludes a serial article on this subject, which she summarizes as follows: "What have women accomplished in medicine since they began its practice?" (1) They have made a large proportion of permanent contributions to medical science, especially if we take into consideration the fact that historically they have always been in a minority in the profession; and (2) repeatedly crowded back and even out of the profession by the aggressiveness and numbers of their medical brethren, they have as repeatedly —and let us hope at last permanently—proved their ability to compete on equal terms with a fair degree of success and at least an average proportion of scientific achievement of the first rank. They have done this in spite of a most obstinate spirit of opposition on the part of their medical brethren; in spite of the seemingly insurmountable obstacles placed in their path by dogged masculine determination. Their courage has been dauntless, each attack more determined than those preceding and actuated by the keenest sense of justice and of fair play.

1. **Adenomyoma of the Rectovaginal Septum.**—Thomas S. Cullen. (See MEDICAL RECORD, June 17.)

2. **Peter Parker, the Founder of Modern Medical Missions.**—C. J. Bartlett says that the laying of the corner stone of the hospital for the Yale Medical School in Changsha, China, which occurred some few months ago, makes this a fitting time to recall that this work is the natural outgrowth of that begun by another Yale man eighty years ago. His name was Peter Parker, and to him belongs the distinction of being the founder of modern medical missions. The writer reviews the biography of this remarkable man, picturing him as a student in both the divinity school and medical school at Yale and describing both his medical and missionary work in China. His great work began with the opening of the Ophthalmic Hospital in Canton in November, 1835, as a missionary hospital. This institution was forced to extend its scope so as to include general surgical cases. A number of unusual cases occurring in the early history of the hospital are reported. Of special interest in this connection is a collection of between eighty and ninety oil paintings illustrating surgical conditions as Dr. Parker found them in China. When the first commissioner to China reached there in 1844 he appointed Dr. Parker as secretary to the legation, and from that time he added onerous diplomatic undertakings to his missionary and medical work. This biography is of particular interest because of the emphasis that it places on Dr. Parker's greatest accomplishment. He was a missionary in the strict sense of the word, and a diplomat of no mean order, but his chief contribution to the spread of civilization was as a medical man in founding medical missions. This article is of further interest in setting forth those qualities of mind and heart which should form the ideal of one who would choose this field as a life work.

3. **Effects of Heat on the Eye.**—William E. Shahan describes his experiments on animals made to determine the physiologic limit of heat tolerance for stated lengths of time and the thermaphor which he used in making the experiments. It is evident from these experiments that the *substantia propria* has no sharply defined limit of physiological tolerance to heat, but that the effects on it vary increasingly with increase in the intensity of the heat applied. It would appear, however, that 130° F. (54.4 C.) is as high as it is safe to go without producing gross permanent changes. There seems to be excellent theoretical reasons for believing that the cornea will stand more heat than certain invading organisms, such as the pneumococcus of ulcus serpens that have a relatively low thermal death point. Experiments in ulcus serpens indicate that any temperature up to 130° F. applied directly to the ulcus serpens for ten minutes has no beneficial effect whatever. It is probably even harmful. The writer believes, however, that before heat is discarded as useless in these conditions it is necessary to investigate another method of using it, namely, that of applying higher degrees for shorter lengths of time. An investigation of this kind is now under way.

6. **A Plan of Treatment in Infantile Paralysis.**—Robert W. Lovett presents a plea for a definite uniform plan for the treatment of infantile paralysis in all of its stages, for a direct attack on the disease based on its pathology, and for persistency and precision in that therapeutic attack, with special care as to the avoidance of fatigue from over-exercise and over-treatment. It is the belief of the author that nowhere in orthopedic surgery does the difference between the best and indifferent treatment have more effect on the ultimate result than in this disease. During the first stage of the disease the essayist emphasizes the importance of quiet and advises that the feet be kept at right angles to the legs to avoid the most common deformity, dropped foot. Toward the end of this period, which may be assumed to have ended when tenderness has disappeared, immersion in a warm salt bath is desirable. During the second stage, which may be assumed to begin with the disappearance of tenderness and to last for two years or more, the problem is to restore the maximum function to the affected muscle and to study most carefully the measures most likely to accomplish this end. With the acute stage over it is on the whole desirable to get the patient on his feet, *i.e.* to institute ambulatory treatment. In the writer's opinion muscle training is the measure of greatest value at this stage, being one of the most powerful factors in determining ultimate muscular function. It should always be borne in mind that fatigue and overtreatment by massage and exercise are detrimental factors of the highest importance too little attended to. During the third or stationary stage, the requirements of the preceding stage as to care of the muscles still exist but are less urgent. Even in this stage muscle training may accomplish much.

The dominant requirements of this stage are operative, and are, first, the correction of the deformity, and, second, operations to improve function and secure stability. Finally the author discusses the various operations that have been employed for the improvement of function.

8. **Focal Infection in Relation to Certain Dermatoses.**—M. L. Ravitch reports ten cases of skin disease in which the etiology was obscure and which were resistant to treatment, and in which the discovery and removal of a focal infection resulted in a disappearance of the dermatosis. He states that he might have cited many more cases. In commenting on these cases, he says that not all systemic and skin derangements are due to focal infection. A great many obscure diseases may be traced to faulty internal secretion, which offer a great field for the clearing up the etiology of obscure diseases; but, again, faulty internal secretions may be due to focal infection. All these things teach one to be on his guard and to make thorough examination in doubtful cases. The skin should be considered not as surface only, but as a cutaneous organ, as capable of infection from within as any other organ.

1. **An Inquiry into the Natural History of Septic Wounds.**—Kenneth Goadby has made a study of the bacteriological flora of wounds from the moment of admission to the hospital, and subsequently through the various stages of the illness, correlating the bacteriological knowledge with the clinical symptoms, surgical treatment, and sequelæ. The condition of the blood was also studied in relation to the degree and variety of sepsis, and particular attention given to the benefit or otherwise of the use of bacterial vaccines. As the inquiry progressed other problems related to the persistence of unhealed wounds with sinus formation, and the appearance of general disturbance with secondary attacks of fever and inflammation, often associated with trivial surgical interference with the wound, demanded special attention. The inquiry is divided into three main lines of research, necessitating the division of the report into three sections, namely, (1) Sinuses and sinus formation; (2) Vaccine therapy and wound infection; (3) General tissue reactions in wound infection. In the first section of the report the author concludes that there is a preponderance in infected wounds of certain classes of anaerobic bacteria—namely, organisms referable to the groups: 1. *B. œdematis maligni;* (2) *B. perfringens* (Veillon); and (3) *B. hibler;* that there is a small incidence of *B. tetani*, at present only in cases of clinical tetanus; that wounded tissues, especially sequestra, contain anaerobic bacteria months after the original injury, even when the external wound has healed; that infection of the wounded and partially healed tissues with anaerobic bacilli predisposes to sinus formation; that persistent infection of the wounded tissues is the chief, if not the essential, factor of the "flares" occurring after operations upon sinuses; that the use of appropriate vaccine therapy is an important and urgent concomitant of surgical treatment in the prevention of "flares" after secondary operation, and in the prevention of sinus formation and secondary hemorrhage; that the biological activity (digestive activity) of anaerobic bacilli is more important than the specific infectivity. As a result of his investigations into sinus cases generally the author suggests as a routine treatment of chronic sinuses resulting from gunshot and other projectile wounds that the case be treated as though anaerobes were present. An autogenous vaccine, preferably a sensitized one, should be made from the organisms in the sinus; streptococci and the coli or proteus group must be included when present. Such cases should not be operated upon until efficient immunization (three weeks at least) has been carried out. From the results recorded in this report it would appear that the anaerobic bacteria, even if present in the sinus, may be disregarded, provided precautions are taken to immunize the patient before operation and to provide an efficiently drained wound. All chronic sinuses which alternately heal and break down should be treated by vaccine therapy before subsequent surgical procedure is adopted.

2. **Digitalis in Aortic Incompetence.**—Seymour Taylor records further experiences confirmatory of opinions that he has previously expressed as to the effect of digitalis in aortic incompetence. He states that as he lives longer and sees more cases, and registers the results of treatment, or the failures and successes of prognosis, he becomes more impressed with the value of clinical experience as against theories of the laboratory or the seductive whisperings of a physiological instrument. The writer has for many years recorded the life histories of patients who have suffered from aortic regurgitation, recorded their longevity, their mode of death whether lingering or sudden, and compared a series of cases treated with digitalis, and another series of cases in which the drug has no place in the defense. He finds that sudden death in the cases treated with digitalis is by no means uncommon. If in addition to aortic insufficiency the patient has also mitral regurgitation, then digitalis is a useful remedy. The chief object of this present communication is to put on record some additions to the number of cases having aortic regurgitation who have survived to old age and to whom digitalis has never been given, though he has had them under his care for ten to fifteen years. In cases having attacks of dyspnea and requiring medication he has treated successfully by small doses of trinitrin (gr. 1/200), and a very diminished dietary, usually about a third of the daily amount, with one day's fasting each week.

4. **Indications and Contraindications in the Pneumothorax Treatment of Pulmonary Tubercle.**—Clive Riviere states that pneumothorax treatment should be borne in mind as soon as ulcerative processes appear in the lungs and where life is threatened, but it must not be postponed until life is in danger, for it is mostly then too late. The high function of pneumothorax therapy is to restore the lost cases to health; but the bad outlook must be recognized in good time if pneumothorax treatment is to succeed. A phthisis case may be to the initiated "lost," so far as ordinary methods of treatment are of avail, long before the end is in sight. It is at this stage, and even before, that the suitability of pneumothorax must be decided upon if a clear other lung, absence of widespread adhesions, and a reexpansible lung are to be with any likelihood attained. On the other hand, it must be admitted that the advanced, apparently unilateral, hilus tuberculosis cases are seldom met too late for this treatment, and it is remarkable how often the pleura remains sufficiently unadherent to allow the production of an efficient pneu-

mothorax over disease extending even from apex to base. The writer mentions the following contraindications to pneumothorax, bilateral involvement, advanced emphysema, asthma, disability of the circulatory organs and kidneys, intestinal tuberculosis, and diabetes. Dyspnea in itself he does not consider a contraindication; neither does he consider laryngeal tuberculosis a contraindication unless very advanced. Pneumothorax may be an emergency operation for bleeding otherwise uncontrollable and likely to prove fatal, or it may be undertaken for some cases of recurrent hemoptysis.

6. **Early Ether Analgesia.**—D. P. D. Wilkie recommends a method of producing ether analgesia for minor operations for which a local anesthesia is unsuitable and where the aparatus for administering nitrous oxide and ethyl chloride are not available. His method of producing brief analgesia is, after having made all preparations for the operation, to place a Shimmelbusch mask over the patient's face and to pour 3 drachms of ether over the mask and bring a folded towel over the face and mask and keep it closely applied. It will be found that in from thirty to fifty seconds, provided the patient breathes deeply and regularly, the stage of analgesia has set in and will last from fifty seconds to three minutes, the usual duration being slightly less than two minutes. The writer finds this method suitable for such minor operations as incision and scraping of multiple abscesses of the neck, removal of septic ingrowing toe-nails, circumcision, cutting of projecting portions of two phalynges with bone forceps, etc. The patient is usually able to walk out of the operating room and feels no unpleasant after effects.

1. **Some of the Principles and Problems Related to the Treatment of Gunshot Fractures.**—Hey Groves writes from his experience in the Queen Alexandria Military Hospital, where he was also entrusted with the founding and administration of a central splint factory which has brought him in contact with a great number of medical officers and the various conditions under which military surgery has to be undertaken. In his opinion the plan of having a factory where fracture apparatus can be made on the premises of the hospital is a simple, efficacious, and economical plan which should be adopted by all large military hospitals; it encourages the trying of new ideas, and the treatment of severe gunshot wounds under modern conditions presents new problems that require solution. It has been well said that every severe case of gunshot wound complicated by fracture presents two stages. In the first there is a wound complicated by a fracture, and in the second there is a fracture complicated by a wound. At no stage can either be neglected, yet the infected wound claims first attention, and that until it has been restored to a healthy and healing condition. From the earliest possible moment, and until bone union is firm, the limb must be immobilized and placed in such a position that the wound can be frequently dressed without moving it or without changing the relative position of the bone fragments. Having secured immobilization, the main points in the treatment of the wound are that within forty-eight hours every wound, except the clean through-and-through bullet wound, should be disinfected by excision and the removal of foreign bodies. At a period of a week or ten days after the injury disinfection of wounds seems hopeless and a selective method must be adopted, leaving those alone in which infection is quiescent and opening up those only in which it is active. It is easy to state this principle but a matter of some difficulty to carry it out correctly. There is no doubt that a ragged shell wound with a retained missile must be opened up early and freely, and, equally, that clean perforating wounds should be left alone, but there is a large class intermediate between these which gives trouble and anxiety. The only safe rule to follow would seem to be to open up all cases in which there is any doubt. An irregular temperature, local tenderness, a rising leucocyte count, and an infection by the streptococcus, B. pyocyaneus, coliform or gas-producing bacteria, are all facts which require immediate operation. In cases in which it is not possible to open up deep pockets and in which if a tube only is left a troublesome sinus results, whereas gauze packing is painful and difficult, a special plugging instrument has been found very helpful. This device was invented years ago for packing the uterus, and consists of a metal tube and a stylet terminating in a Y-shaped fork. The tube is inserted at the bottom of the cavity to be packed and the ribbon gauze is pushed in by the stylet. The writer expresses no opinion as to the relative advantages of various antiseptics, as his experience has consisted largely in the treatment of cases ten days after injury, at which time mechanical drainage and lavage must be the all-important elements of treatment by which the tissues can disinfect themselves.

4. **A Method of Treatment of Shell Shock.** — E. T. C. Milligan describes a well-known treatment of hysteria which has been used successfully in the treatment of shell shock. This consists in the administration of chloroform slowly, in a quiet room and apart from other patients, and when a suitable degree of anesthesia is induced in suggestion carried out by the anesthetist. In all types of cases suggestion is continued until the patient has fully recovered consciousness. When quite rational the man is assured of his cure, promised a rest, given morphine, and allowed to enjoy a much-needed sleep. The aftertreatment consist of prolonged rest and change of surroundings. Cases of loss of memory, loss of speech, loss of hearing, hysterical attitudes of the limbs, and loss of function have been successfully treated in this way.

La Presse Médicale.

July 20, 1916.

Application of Pachon's Method to the Study of the Cardiopulmonary Circulation.—Colleville quotes Naegeli as stating that tuberculosis appears at puberty in 96 per cent. of individuals. The hardships of the present war may increase the number of cases of active tuberculosis to a "shuddering" extent. We must be prepared to recognize incipient and quiescent cases, and recently it has been stated that Pachon's oscillometer and Schick's cutireaction are likely to form the best routine methods for this purpose, the former being especially calculated to reveal the lowered blood tension of the tuberculous. The author appears to have devoted himself chiefly to the question of recovery from tuberculosis in the troops. Oscillographs reveal nerve depression, and the influence of the innervation upon the cir-

culation is of the greatest significance for the tuberculous. In the nontuberculous with nervous depression it is impossible to increase the respiratory capacity, and they rebel against all exercise. If either a physical or psychical stimulant favorably modifies this state of adynamia it is at once shown in the oscillograph, which first shows overactivity and then assumes the normal. The same law is in evidence in the nervous tuberculous subject. Bearing in mind that respiratory capacity depends in part on the elasticity of the lungs as well as on the intrapulmonary circulation, these two factors must be studied in common. In lungs which retain their elasticity respiratory gymnastics are in order; in others we must use an excito-cardiac medication, such as cachets of sweetened camphor. A tuberculous subject is not fatally deprived of power of ventilating his chest. It is to be hoped that oscillographs may be made to afford a basis for a classification of tuberculous subjects.

Forearm Prosthesis.—Ducroquet discusses this subject extensively in connection with amputations of the forearm. There should be three so-called points of fixation in the latter, viz., the point of support for the apparatus, which is the lower part of the arm; the point of counter-ascension, the upper part of the forearm, and the elbow joint. In other words, we have the forearm prosthesis, which covers and protects the stump; an armlet for the upper arm, and a hinge mechanism connecting the two, with perhaps a sling over the shoulder. This apparatus is, of course, old and simple, and serves but as a base for special prosthesis. For the mechanic an artificial hand is, of course, out of the question. The object of prosthesis at present is to invent apparatus to enable him to work at his trade. The simple hook may be used by various kinds of laborers, but each man must have more than one kind of apparatus. The gardener uses a special ring which plays in a sort of stirrup, also a spade holder. The vinedresser needs a pruning hook to immobilize branches which have to be cut or sawed away. The chauffeur can employ a so-called "bell" as a substitute for his closed hand on the lever of his machine, the bell being held in a fork. A single apparatus is in use for holding saws and hammers. A complete set of apparatus has been devised for brushmakers. On the other hand, the commercial traveler requires no technical prosthesis but a specially articulated hand with considerable prehensile ability. Many inventors appear to be occupied in perfecting special forms of prosthesis.

Le Bulletin Médical.

July 21, 1916.

Elie Metchnikoff.—Roux, long the chief assistant of the deceased scientist, gives some reminiscences concerning the latter which are not contained in the numerous necrologies. Three minutes before the end came Metchnikoff was conversing with Roux and others. By advice of Widal, his physician, he had taken to his bed three days before. Death occurred from syncope due to a slight change of position. The entire period of treatment was seven months. In May, 1915, when he had attained his seventieth birthday, the officers of the Pasteur Institute held a celebration in his honor. Roux, who was unable to be present, addressed a letter to his colleague in which the latter's great services to science and humanity were reviewed. His seventy years were pronounced a short term for the work accomplished by him, which was sufficient to have made several men eminent. After the reading aloud of this letter Metchnikoff conversed familiarly with his colleagues on the subject of longevity. He spoke of having reached the end of his career. The statistics of the Italian Bodio furnished the proof that the Psalmist's estimate was in the main correct. He was fortunate in having attained it, for longevity was hereditary and none of his immediate relatives had reached such an age. He spoke of Lister, who died at eighty-five, his father at eighty-three, and his paternal grandfather at ninety-three. That he was alone among his own relatives to reach seventy he ascribed to the carrying out of his own theories of combating autointoxication. He mentioned especially Welch's bacillus as an implacable enemy of mankind, not only to the wounded in the present war but to all in times of peace as well, as an intestinal denizen. He had used the lactic acid bacillus for some eighteen years as part of his food regimen. The science of longevity is in its infancy and we are as yet ignorant as to why the aged die at so great a rate from pneumonia and malignant growths. What we seek at present is not great longevity in the individual but how to cause all men to reach the age of seventy. As for cancer, he believed firmly in its exogenous origin. He would like to see two plans of prevention carried out in the elderly, to wit, sterilization of all food and absolute cleanliness of the skin. As another preventive factor against premature senility he advocated a suitable mental state, freedom from pessimism and from fear of death and disease. In this connection he quoted Tolstoi, who in speaking through certain characters appeared to regard the prospect of death as sufficient to destroy all ambition and endeavor. The desire to live may vary inversely with the age, but the cessation of this desire should be natural only in those who have reached advanced years and with it a satiety of life. In the future the old man may succeed better in retaining the full possession of his faculties and with it the desire to live. The great war is mentioned in this connection, as if it had produced conditions which militated for the time against progress in the science of macrobiotics, but the interruption will only be temporary. The great scientist's body was cremated and his ashes will rest in the Pasteur Institute in a large urn of red marble.

Death Following a Sting by a Wasp.—Recently death occurred to an engine room artificer of Portsmouth, England, who had been stung by a wasp while sleeping on board his ship. The swelling of his neck was so great that he had to be sent to the Haslar Hospital, where he died on the following day. At the inquest Surgeon Caldwell Smith ascribed death to bacterial infection caused by the wasp's sting. The deceased was a healthy man, hence the virulence of the infection must have been extreme. A verdict of accidental death was rendered.—*The Medical Times.*

The Corroborative Diagnosis of Mastoiditis by Means of the X-Ray.—Harold Hays says that the diagnosis of mastoiditis, as a rule, can be made readily from both the subjective and objective findings. Such further data as those observed by the *x*-ray are not necessary. Yet we are inclined to make use of every aid to confirm our diagnosis, particularly in those doubtful cases in which the question arises as to the advisability of operation. The majority of the cases of mastoiditis are operated on without the corroborative evidence of the *x*-ray picture. In those cases which do not respond to treatment, and where certain complications are set up, such as sinus thrombosis and epidural abscess, the *x*-ray findings will frequently determine the condition of the underlying bone before extensive destruction has taken place. Proper *x*-ray pictures of the mastoid are of decided value in determining the necessity for immediate operation.—*New York Medical Journal.*

Book Reviews.

CANDY MEDICATION. By BERNARD FANTUS, M.D., Professor of Pharmacology and Therapeutics, College of Medicine, University of Illinois, Chicago. Price, $1.00. St. Louis: C. V. Mosely Company, 1915.

DR. FANTUS' little book on candy medication belongs primarily to the prescription pharmacist and the country practitioner who must dispense his own drugs, for it gives in detail the method of preparation by which a number of drugs may be given in candy form. However, the introduction of the book and the method to the pharmacist will depend largely on the physician and especially the pediatrist. Up to this time the most palatable doses have been prepared by the large drug houses. This new method of prescription preparation which Dr. Fantus presents should prove useful for the ill-controlled adult patient as well as for children bebetween 3 and 10, as Dr. Fantus suggests. He gives formulas for fifty-seven medications, but on looking through the list one finds rather a large number which would be infrequently used for children. No doubt other drugs will be added to the list in the near future. It would seem a definite mistake to give hexamethylenamine in the form of candy tablets. This drug irritates the kidneys unless given with the sufficient amount of fluid. If a patient is given tablets, there is no assurance that the necessary amount of water will be taken, and, moreover, hexamethylenamine is entirely tasteless in the proper amount of water.

THE AFTER-TREATMENT OF OPERATIONS: A MANUAL FOR PRACTITIONERS AND HOUSE SURGEONS. By P. LOCKHART-MUMMERY, F.R.C.S., Eng., B.A., M.B., B.C. Cantab. Senior Surgeon, St. Mark's Hospital for Cancer, Fistula, and other Diseases of the Rectum, The Queen's Hospital for Children, London, and Honorary Surgeon to King Edward VII Hospital for Officers; Special Consulting Surgeon to City of London Military Hospital and Fulham Military Hospital; Jacksonian Prizeman, and Late Hunterian Professor, Royal College of Surgeons. Fourth Edition. Price, $2.25 net. New York: William Wood & Co., 1916.

THIS book, which has already reached its fourth edition, is one that should be of much value to at least three classes of readers—nurses, members of house staffs, and general practitioners, particularly those in the country who are often called upon to operate when no expert surgeon is available or who must look after the patient after the operation itself has been done by a consulting surgeon. We may also say that there are comparatively few surgeons, with the possible exception of those connected with an active metropolitan hospital service, who will not find many valuable suggestions in this little book; for the text is written by an experienced surgeon of world-wide reputation and embodies, to a large extent, the methods he has himself found most efficacious. The book has been brought up to date in many ways. As evidence of this we find a short but remarkably meaty chapter on the treatment of gunshot wounds, while the chapter on surgical shock has been rewritten and the influence of Crile's recent teachings is very manifest.

Books of this sort are needed; for we thoroughly agree with the author in the statement that it has become too common to think that the operation is everything and that the after treatment is merely a matter of course. On the contrary, while, as he says, the operation is the most showy part of the treatment, many a case is saved or lost through skillful and careful or careless work on the part of the doctor or nurse after the operation itself has apparently been successfully done. This is one of the books with a mission; and the nurse, interne, or practitioner who is familiar with its teachings will save many patients who might otherwise be lost and will certainly make a host of others more comfortable during their convalescence.

THERAPEUTIC BY-WAYS: Being a collection of therapeutic measures not to be found in the text books. Collected from all sources. Condensed and arranged. By DR. E. P. ANSHUTZ. Price, $1.00. Philadelphia: Boericke & Tafet, 1916.

EVEN though we have not the faith in the doctrine of similars and in the efficacy of high potencies, we may read much of interest in Anshutz's "Therapeutic By-Ways." He has had patience for years to gather from the men and books which passed his way, and much from past superstitions has gone into his little book. His one very sensible comment on experimental pharmacology is the following: ". . . for why may not the infinitesimal do that which the crude and the palpable may not do? Does man, in this day, still hold to the belief that because he cannot see a thing it does not exist? If he does he kicks over the best in modern science and makes his senses the arbiters of science."

TONSILS AND ADENOIDS: TREATMENT AND CURE. From the Standpoint of the Physician and Laryngologist. No Preference to that of the Surgeon and Laryngectomist. By RICHARD B. FAULKNER, M.D. (Columbia University). Price, $1.00. Pittsburgh, Pa.: The Blanchard Company.

THE TONSIL AND ITS USES, VOCAL, MECHANIC AND PHYSIOLOGIC. By RICHARD R. FAULKNER, M.D. (Columbia University). "The tonsil is an organ that must be respected."—Lermoyez. "You have no right to destroy it."—Von Levinstein. "It is absolutely necessary in the modulation of the singing voice in crescendo and diminuendo."— Lamperti. "It is the sound-post in the mechanism of speech and song."—The Author. Price, $1.00. Pittsburgh, Pa.: The Blanchard Company.

THESE two books are so closely related that it seems suitable to notice them together. The pamphlet on tonsils and adenoids is one of brief statements and references to the author's larger book. The "Note" on the first page reads: "The figures in the body of the text refer to pages in my book on 'The Tonsils and the Voice.' The reader is advised, in every instance, to refer to the page indicated and read what is there set forth," and ninety-two page references are given in twenty-three pages! The book has, however, some excellent advice as to the treatment of diseased tonsils, and Dr. Faulkner's association with those to whom the voice is of such vital importance gives his opinion weight.

The author seems given to superlatives, and such statements as "Pain anywhere not associated with increased temperature must be looked upon as reflex," can scarcely be accepted. What about the more than occasional gangrenous appendix where there is no rise of temperature for several hours after the beginning of pain? And the headache of hypophyseal tumor is certainly not reflex according to his use of the word.

One-third of "The Tonsil and Its Uses" is taken up with quotations from medical and musical people. One of the author's deductions is that "persons who have large tonsils are generally healthy." Such a statement needs indisputable statistics to back it. However, when all is said, Dr. Faulkner is working in the right direction—toward the intelligent medical treatment of diseased tonsils as against indiscriminate tonsillectomy and tonsillotomy.

MANUAL OF VITAL FUNCTION TESTING METHODS AND THEIR INTERPRETATION. By WILFRED M. BARTON, M.D. Associate Professor of Medicine, Georgetown University, Attending Physician to Georgetown University Hospital. Price, $1.50 net. Boston: Richard G. Badger, 1916.

THE author has collected from the literature the methods for testing the functional capacity of the liver, kidney, pancreas, heart and the ductless glands and has thereby rendered a great service to the many who lack the time and energy to search them out independently. While in several instances the methods are described with insufficient detail, nevertheless the references are given and those unfamiliar with chemical methods can find the technique in full in the original sources. The book is a welcome one and should find a wide circle of readers. The discussion of the value of the various tests described is, as a rule, brief and well-considered and the author has not allowed his enthusiasm to warp his judgment.

THE MEDICAL CLINICS OF CHICAGO. May, 1916. Volume I—No. 6. Published Bi-monthly. Price, $8 per year. Philadelphia and London: W. B. Saunders Company.

THIS number closes the first volume of the Medical Clinics, and a comparison with the first number shows a very definite improvement during the year. The number of cases discussed in a single issue has decreased, and there is more thorough discussion of the conditions presented. In this issue there are presented about eighteen cases from ten clinics. There are very interesting discussions of the Allen treatment of diabetes and of rickets, although in the latter the blood changes which may appear in the course of the disease are not adequately pictured. There is appended a very complete index for the volume.

Society Reports.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, Wednesday, June 7, 1916.

THE PRESIDENT, DR. RICHARD H. HARTE, IN THE CHAIR.

Glucose Formation from Protein in Diabetes.—Dr. N. W. JANNEY of New York in this communication emphasized the importance of the exact knowledge of the maximum extent of glucose formation from protein in diabetes for the clear understanding of the glycosuric process and its dietary treatment. Various criticisms he said could be offered to previous experiments to this end which had been made upon human diabetics and depancreatinized dogs. A critical study of phlorrhizin diabetes had led to the conclusion that glucose formation from protein in this condition represented essentially the same process as that occurring in the human glycosuric subject. Therefore a technique had been developed permitting of quantitative determination of the amount of glucose arising from protein fed to animals made completely diabetic with phlorrhizin. The results so obtained were applicable to the problems presented by diabetes mellitus. It could thus be actually demonstrated experimentally that 58 per cent. of glucose as a maximum could originate from the body proteins of man. This corresponded to the urinary glucose (nitrogen ratio 3.4:1), which was of diagnostic value. If the glucose excreted by fasting diabetics should show this relation to the nitrogen, the severest form of diabetes was present. The more nearly and the more quickly the G:N ratio approached 0:1 on fasting, the more favorable the diagnosis. In these experiments, he observed, it had also been shown that practically all the sugar, and *no more*, excreted by fasting completely diabetic animals arose from protein. It was therefore evident that glucose formation from fat in diabetics was inconsiderable. By use of the new method of experimentation a series of pure isolated proteins had been found to yield large amounts of sugar in metabolism varying from 48 to 80 per cent., according to the protein examined. Contrary to existing opinions, the animal or vegetable origin of proteins was found to bear no relationship to their ability to produce glucose in the animal organism. Variations in the amounts of sugar arising from individual proteins were essentially due to the differing amounts of glucose yielding amino-acids entering into the make-up of the protein, although certain alimentary factors influencing digestion also played a rôle.

In another investigation glucose formation from various meats had been similarly studied. Beef, rabbit, fish (halibut), chicken, and eggs were found to give rise in the diabetic organism also to considerable amounts of glucose, 36 to 48 per cent., calculated for water-free solid material. It could likewise be ascertained that from bread 61 per cent. of sugar was formed in the diabetic's body. Von Noorden's food tables for diabetics were regarded by Dr. Janney as very inadequate, since they did not take into consideration the large amounts of sugar arising in metabolism from protein. The new data alluded to rendered it possible, however, to compare the combined amounts of carbohydrate present in and arising within the glycosuric organism from various protein foods to that of bread. An accurate diet table for diabetics could thus be calculated in which was represented the actual relative adaptability to the diabetic dietary of protein foods as compared with bread. It was estimated that approximately 250 to 350 parts of the usual varieties of cooked meats were found to be equivalent, from the standpoint of sugar production, to 100 parts of bread. Eggs were said to present a decided advantage over other forms of protein food, 525 to 600 parts of eggs, whether boiled, raw, or fried, being equivalent to 100 parts of bread. Regarding the glucose production from proprietary protein foods, contrary to the prevailing opinion, the effect of the high protein content of such products was to cause so much sugar production in metabolism that in nearly all cases these gluten and albuminous preparations were more harmful to the diabetic than equal amounts of wheat bread. Since increased glycosuria resulted from ingestion of carbohydrates, proteins, and fats (the latter by indirect action), the author said it was now quite evident that the only way to rest the glycolytic function was to practically abstain from all food whatsoever. The rationale of the Allen fasting treatment for diabetics was therefore emphasized by these researches. In view of the extent of sugar formation from protein, it was also clear that the classical "strict" diet for diabetics should no longer be ordered. A mixed diet containing moderate amounts of protein and fat and low amounts of carbohydrates was said to be more palatable and to present no greater disadvantages than the high protein and high fat diet. The results of chiefly scientific importance obtained in the series of investigations mentioned, Dr. Janney said, had been described in articles which had appeared elsewhere; the detailed results referable to the diabetic dietary were in course of publication.

Dr. JAMES E. TALLEY of Philadelphia expressed his gratification at having a scientific demonstration of the fact that the protein of egg was better borne than other proteins. From experience with patients with poor tolerance for some time after their starvation cure some practitioners had come empirically to such conclusion. He regarded as troublesome problems with these patients satisfying calory needs, the appetite, and the family apprehensions.

Dr. GEORGE M. PIERSOL expressed his interest in having more scientific data concerning the rationale of the Allen treatment, which all agreed had in the last year proven to be the most successful means of combatting diabetes. Since this rationale had always been a matter of conjecture and some controversy, all explanatory evidence was of great value.

Dr. JANNEY, in closing, cautioned that the results given be not taken too positively. They were to be considered, if possible the most reliable known at the present time, still merely as a general guide in the protein feeding of diabetics. To accept that a certain protein should be entirely discarded for another owing to a difference of a few grams in sugar formation was assuming an unwarranted position, owing to the various digestive and other factors involved. When, however, the glucogenetic capacity of one food was strikingly less than that of another—for example, eggs as compared with meats, or meat as compared with commercial preparations high in protein—then it was that the practical utility of this new data became most important.

The Physical Cultural Effect of Preparedness.—Colonel WILLIAM H. ARTHUR, Medical Corps, U. S. A., president of the Army Medical School, presented a paper under this title.

Individualism and Decadence.—Dr. ROBERT T. MORRIS of New York under this caption took up the question of struggle, beginning with the struggle of inorganic elements for place in the periodic table. Struggle occurred, he said, not only between the cells of an individual but between individuals in a family, between families in a town, between towns in a State, and between States in a great organization of States, and that conflict would continue, as it belonged to the laws of evolution. As civilization advanced the periods of peace between large groups of civilized people would be of longer duration, but the warfare and struggle when they did come would be more terrible. He stated that at the present time almost all the Aryan nation groups were declining, but that the progressing Slavic groups were bound, according to the laws of nature, to attack the rest of us at some time in the not very distant future; further, that a nation like Japan, which had formerly been content with esoteric philosophy, would struggle for dominion over the world whenever such a nation developed exoterically. Mass action of the people in a nation of the future would be accomplished through the agency of patriotism. Patriotism, he observed, was a nasty little prejudice given to man by nature, apparently for the purpose of keeping him in herd form in nations, which prejudice was flatly opposed to the beautiful ideal of the brotherhood of man. He believed that there was need for military training in America, provided the people had a sentimental wish to retain their identity as a nation; if not, they might continue in the development of that individualism which led to early decline, rendering them more vulnerable to the attack of a predatory nation, which predatory nations were developing on all sides. The United States of America might be regarded at present as a big, helpless, fat, juicy rabbit waiting to be taken, and the people as too fat to fight. In considering the elements of many nations now included in the people of America it was to be noted that these different elements were being hybridized; crosses were being made between species, which did not give large possibilities for mass action. Plant and animal breeders claimed that specific

hybrids, or crosses between species, did not make durable types. The strongest nations were those belonging to crosses between varieties and not species. In this country, the author said, the people were not crossing species freely. With the introduction of various conflicting elements there was not quite the freedom of which the people of this country had boasted, but a more or less discreet autocracy instead of such concrete autocracy as might belong to a responsible king. The politician exercised a discreet autocracy in every town, hamlet, and State, and there was not the freedom which had been claimed. Furthermore, the people of this country were developing that most valuable and, at the same time, most dangerous trait known as individualism. In the regard for the individual rather than for the State there was occurring that rapid fall in birth rate which belonged to older countries. The birth rate he regarded as a sort of gage which indicated what was in the boiler of a country. Military training was of advantage in that it allowed young men to feel that by mass unit action they were working for each other and for the State. Military training gave them intelligently the idea of mass action, which would hook out the hyphen between this and the older countries. Incidentally it taught them deference to authority and self-control in the interest of personal physical health.

Prof. WILLIAM A. STECHER, Director of Physical Education in the Public Schools of Philadelphia, felt that in the discussion of military training sight was being lost of the fact that the elements of training upon which most weight was placed were not those of which most people were thinking when speaking of military training. A study of the training given to the youth in European nations would show that real "military" training did not begin until the young man entered the army at nineteen or twenty years of age. As soon, however, as the boy—and the girl—entered school, pre-military training began in the form of sufficient and effective physical training. He felt that the recent movement for preparedness had made people realize that which teachers had always known, that physical training had also a mental and a moral end. That which was being asked for under the term "military training" really should be termed "more effective physical training." He would agree not only that every young man should serve his country, but that his training for good citizenship should begin as soon as he entered school. Specific military training in the elementary schools he regarded as entirely out of place, because he made a distinct cleavage between premilitary work and military work. He advocated military training and believed that the medical profession could help very materially in securing in the public schools the type of training fitted for the growing youth. Could boards of education be told by the medical profession that a few minutes of physical training per day would never make a healthy boy or girl, but that they should have from an hour to an hour and a half of physical training per day, in the open air if possible, the country would have young men at nineteen years of age physically fit to join the army.

Dr. A. C. ABBOTT referred to his impressions upon reading "The First Hundred Thousand," the story of a Scottish regiment recruited from men in all walks of life, consisting in the beginning of an ignorant, heterogeneous mob, but after a few months of training becoming a coordinated, well-disciplined, self-reliant fighting machine which gave good account of itself at the opportune time. An advantage equally important, the result of team work in a trained company of men, was the acquisition of ability to take and act upon orders without losing self-respect and learning thereby how to give orders. He would urge the reading of Mr. Maxim's "America Unprepared," which book showed modern warfare to be a matter largely of machinery. In Dr. Abbott's opinion modern warfare had become a new science, demanding special training. He advocated preparedness. He believed in compulsory military service and that the real preparedness should be as full an education in the construction and workings of the modern machinery of warfare as was possible to be given.

Dr. JAMES M. ANDERS felt that physicians should take advantage of every opportunity of pointing out the health value, if nothing more, of training in the camps of the country. He agreed with Professor Stecher that the physical training in the public schools should be carried at least to the level of competent and satisfactory industrial work. Were this done, beyond doubt better material would be furnished for the making of soldiers. He agreed also with the statement of ex-President Roosevelt that military preparedness implied industrial and economic preparedness, and referred to the testimony of Col. E. F. Glenn before the Senate committee to the effect that military drill should begin in the public schools at the age of twelve and should be given for twenty minutes daily for every school day of every year up to the age of sixteen years. Colonel Glenn would not put a gun into their hands during this period, and would not have them called out until they reached the age of eighteen. This, it seemed to Dr. Anders, would be a feasible plan, although not in accord with the views expressed by Professor Stecher, which would make for better preparedness. He emphasized the point that efforts at preparedness should commence as early as possible in life, whether considered from the health, industrial, economic, or military standpoint.

Dr. JAMES TYSON called attention to a line of training apparently too elementary for consideration but which was important—that involved in the ordinary physical acts of walking, sitting, and standing. In this respect girls and boys were too often left to chance, and grew up under conditions favoring deterioration of the anatomy and physiology of the body.

Dr. MORRIS, in closing, said that military training allowed young people to think in terms of the State instead of in terms of the individual.

NEW YORK ACADEMY OF MEDICINE.

JOINT MEETING OF THE SECTIONS ON OBSTETRICS AND PEDIATRICS.

Held March 28, 1916.

DR. GEORGE W. KOSMAK IN THE CHAIR.

Dr. KOSMAK, at the request of Dr. Haynes, the chairman of the Section on Pediatrics, pointed out briefly the reasons why such a joint meeting of the Section on Obstetrics and the Section on Pediatrics should prove of interest and advantage to the members of both sections and to the general practitioner. He stated that the trend of modern medicine had been toward specialism, and that although this development had undoubtedly contributed to the advance of medicine and aided in its transformation from an art to a science, it was essential to remember that the various apparently isolated organic systems of the body were more or less closely interrelated and interdependent. Therefore the practitioner in the special branches of medicine was subject to the same necessity for coordinating his work with that of the immediately related subjects. This was of peculiar significance in the question which was brought up for discussion this evening, namely, "The Care of the Newborn Infant from the Obstetric and Pediatric Standpoints." The obstetrician unfortunately had concerned himself more with the care of the mother than with that of the infant and usually had dismissed the latter from his mind unless some startling abnormality occurred. The pediatrist was necessarily interested in the baby as such and only too often was called in to care for a child with errors of growth and nutrition that might have been corrected or perhaps avoided earlier in its life. The subject of prenatal development was receiving increased attention by research workers, but unfortunately the practitioner of medicine was unacquainted with their observations and their practical application to the human subject had not been extensively made. In the lower animals several investigators had shown the effects of injurious substances on the development of the embryo and within the past year Werber had succeeded in producing deformities of the most varied type, such as cyclopia, ear defects, hydrocephalus, and alterations in the circulatory apparatus by exposing the fertilized eggs of one of the teleost fishes to oxybutyric acid and to acetone. These experiments led one to believe that possibly various toxic products in pregnant women resulting from altered metabolism might account for departures from normal fetuses at birth or even for defects that manifested themselves in individuals later in life. Such imaginings brought one into the field where it was difficult to distinguish between fact and fancy, but they should lead to further experiments on higher animals and to more detailed observation on the human subject. It was in such fields as these that the obstetrician and the pediatrician must extend their attention, for by correlated work it would be possible to contribute something more definite than the fanciful theories referred to

which would in time make for the betterment of the race. Dr. Kosmak said he hoped that this meeting and similar ones would tend to bring these two specialties closer together and by their united work bring the subjects to be discussed more prominently before the general practitioner.

Correlation of the Pediatrist and Obstetrician.—Dr. Roger H. Dennett presented this paper in which he stated that in no other branch of medicine was there a specialty which called for both surgical technique and the peculiar mental attitude of the internist. These two specialties had been combined in a mediocre sort of a way, but no single individual had ever achieved eminence in both. Ever since specialism had developed it had been the custom for the obstetrician to take care of the newborn baby from birth until the second, third, or fourth week of life. The pediatrician had been the consultant only, called in when things went extremely wrong. Dr. Dennett said there was not in New York City, to his knowledge, a public lying-in service, large or small, or a private obstetrical institution, in which newborn babies were visited each day by a pediatrician, just as the mother was cared for by an expert. There could be no question but that the study of congenital disease was one of the most neglected, and at the same time most needed, phases of medicine. Here was the first reason why the pediatrician should have the care of infants from birth. A second reason was that the mortality could in all probability be enormously reduced if proper attention were given to these diseases. Finally, infant morbidity and its peculiarly distressing accompaniments might be lessened during the first year by preventing many cases of malnutrition and gastro-intestinal disturbances. The Bureau of Child Hygiene of the New York Department of Health was now making an investigation of the subject of the early mortality from congenital diseases and had shown that 40.3 per cent. of all the deaths under a year were due to congenital diseases, whereas the deaths from respiratory or diarrheal diseases were little more than one-half that number, 23 per cent. The Health Department further stated that 70 per cent. of all deaths due to congenital causes might be classed as preventable, and that 48 per cent. of these deaths occurred in the first ten days of life. When it came to the subject of morbidity, statistics were less available, but it was probably the general opinion of pediatricians that at least 50 to 75 per cent. of all their difficult feeding cases could have been averted had the pediatrician had the opportunity of supervising the infants' fare from birth. Though there might be some question as to the advisability of the obstetrician turning over all his infants at birth to the pediatrician, there could be no question but that both the infant mortality and morbidity might be lowered by doing so when the infant was two weeks of age. That was, whenever the obstetrician discharged the mother he might recommend that a pediatrician be consulted who should give the infant a thorough physical examination and also give dietetic and hygienic advice for future use. The follow-up work which the Babies' Welfare Association was now doing was a step in the right direction so far as public institutions were concerned. This organization had cared for four thousand cases last year, and this year the numbers were growing as the work was becoming better known. In the opinion of the essayist the proper correlation of the pediatrician and the obstetrician might be brought about in the following ways: (1) By giving as much careful attention to the appointment of the pediatric staff of the lying-in hospitals as was given to the appointment of the obstetrical staff. (2) The pediatrician once having been appointed should make his daily rounds and study and observe his cases from a clinical, laboratory, and pathological standpoint, as he was now doing in his own children's and babies' wards. (3) The obstetrician should educate the laity to expect his duties to end, so far as the infant was concerned, after it had been washed and dressed, with the possible exception of the care of the cord. (4) If the obstetrician cared for the infant as well as for the mother up to the time that the mother's convalescence was completed, he should recommend that the infant be then put in the care of a pediatrician.

On the Need and Value of Systematic Prenatal Care.—Dr. Ralph Waldo Lobenstine read this paper in which he said that to be of real value prenatal care must be systematic, intelligent, and untiring. The whole scheme of prenatal care must begin with intelligent understanding and cooperation on the part of the expectant mother. In order to accomplish the best results not only must the women of the community be aroused but the doctors themselves. There had been a failure to recognize the fact that prenatal care would prevent the development of, or at least lessen the frequency of, many of the serious complications of pregnancy, would prevent many unnecessary maternal deaths, would prepare the mother for labor, lessen invalidism, and exert a deep influence on the welfare of the infant. It was truthfully claimed that 90 per cent. of American women were absolutely without proper prenatal care. Of all the progressive countries the United States was the most backward in this regard. The finest skill at the time of delivery might not and frequently did not save the life of the child, or even that of the mother, when prenatal care had been insufficient or entirely wanting. Health statistics were particularly difficult to deal with in this country because of the incomplete registration area and because even in this area birth records and still-birth records were very incomplete. We had practically no record of the large number of abortions, spontaneous and induced, that occurred annually. Bacon of Chicago, however, in a careful statistical study, estimated that annually approximately 80,000 infants lost their lives at the time of birth or during the first two weeks post partum as the result of injury at the time of birth. If to this number were added those that died *in utero* prior to the onset of labor, there was probably an annual loss to the country of 150,000 infants. To this number must be added the great number of early miscarriages, which, when spontaneous, were more or less dependent on the same causative factors as were to be found in the case of the non-traumatic still-births and subnormal infants. According to the Children's Bureau in Washington among all babies dying under one month of age nearly three-quarters died of causes operative before birth. In the larger proportion of cases these causes were malformation, congenital debility, premature birth, and injuries at birth. The causes of death in the newborn during the first four weeks of life appeared then to be due not to diseases successfully attacking a previously healthy child, but to physiological unfitness in the newly born to maintain an independent existence. Actual death was one thing, but we had another problem in the child that lived for a while or for many years, immature in body and mind, or actually deformed. These abnormal or subnormal beings were thus partly because of causes over which we had more or less control, and partly because of factors arising in the course of pregnancy over which we might at times be almost powerless. The more common antenatal causes of death were syphilis, alcohol, renal and cardiac disease, sexual excess, deficiency in food supply of the mother, subnormal state of the father, as well as of the mother, at the time of conception, and bad physical environment during pregnancy. The less tangible antenatal factors were gonorrhea, the heavy use of tobacco, opiates, and the complex toxemias of pregnancy. The essayist considered these factors more in detail and expressed the belief that even the so-called low grade toxemias of pregnancy were often responsible for conditions of malnutrition, acidosis, and hemorrhagic disease and had received far too little attention. Syphilis and gonorrhea together were responsible for over 50 per cent. of spontaneous abortions and premature interruptions of pregnancy, and in addition for the high infant mortality during the early weeks of life. The evil effects of overfatigue had commonly been disregarded. Freedom from anxiety, particularly during the last six weeks of pregnancy, not only assisted the parturient herself but reacted in a most gratifying manner upon the offspring. The ultimate blame for this high mortality in both mother and child was to be explained by the ignorance or indifference on the part of a large section of the community, in matters concerning parturition; poverty with its perplexing problems; insufficient obstetrical training of the physician; the midwife question, and lack of prenatal care. The remedy lay in publicity without exaggeration, general improvement of social conditions, and in the gradual elimination of the midwife. They should work with this end in view, but in the meantime, an adequate practical plan should be developed in order to offer these poor patients safer medical attention, greater hospital facilities, and more adequate home nursing. National legislation would accomplish much and an ever closer cooperation between milk stations, prenatal clinics, social workers, doctors, and midwives would gradually place the latter in their proper sphere, namely, that of trained obstetrical attendants. The status of the doctor called for serious

consideration. The disheartening conditions to be found among doctors practising obstetrics in this class of the community were due to circumstances brought about partly by faulty training and partly by sociological conditions. If in many instances the doctor was no better than the midwife it was not primarily the doctor's fault, unless he was guilty of criminal negligence. It was a singular fact that so much time was devoted in our medical schools and hospitals to general surgery and so little to practical obstetrics, when the latter would be needed in a far greater degree. It was also strange that so few of our fine general hospitals were willing to receive confinement cases. They seemed to regard obstetrical cases as more or less of a nuisance, and did not appreciate the importance to the community of the proper care of these patients. Every woman should find it possible to obtain regular, systematic, prenatal care during the greater part of her pregnancy and should be urged to seek this guidance and to seek it early in pregnancy. The best solution of the question of the care of maternity cases in their homes might prove to be some form of industrial insurance, such as was being carried out, for example, at the present time by the Metropolitan Life Insurance Company.

Accidents and Diseases of the Early Weeks.—Dr. L. E. LaFétra read this paper in which he said that injury of the infant was the result of prolonged labor, especially dry labor, difficult forceps extraction, abnormal presentations, and difficult extraction of the aftercoming head. Injury also resulted from compression of the umbilical cord, particularly when the cord was tight around the neck. Forceps were less a cause of injury than failure to use them early in case of difficult labor. The essayist then discussed injuries under three groups, those affecting the head, the neck, and the extremities. In discussing injuries of the head, he pointed out that cephalhematoma might be distinguished from fracture by its limitation to the separate cranial bones and by the fact that the floor of the swelling was on the same level with the rest of the skull. Fracture of the cranial bones was not frequent, was practically always depressed, and was frequently accompanied by signs of intracranial hemorrhage. The elevation of the depressed bone could be accomplished most successfully by the strong hook devised by Dr. Kosmak. The serious injuries to the head were those which resulted in intracranial hemorrhage either meningeal or cerebral. The loss of the sucking reflex was the most important sign of serious brain lesion. Absence of pulsation in the fontanelle was commonly present. Localization of the site of the hemorrhage was often not possible, but when it could be localized immediate operation was indicated. The commonest result after recovery from brain hemorrhage was spastic paralysis of one side of the body or of both extremities. When more than two extremities were involved there was always mental impairment. In discussing injuries to the neck, Dr. La Fétra said that ruptures of the cords of the brachial plexus occurred when pressure or traction was put upon the neck with the head rotated. This resulted in brachial paralysis with flaccid shoulder and inverted hand hanging limp at the side. Dr. Alfred Taylor had secured good results from operating on some of these bad cases. The essayist then called attention to the congenital defects to which the newborn infant was subject, such as congenital heart disease, congenital hypertrophic stenosis of the pylorus, spina bifida, cleft palate and hare lip, club foot, chondrodystrophy and Mongolism. Constitutional disease was shown specially by syphilis, but also by sclerema and general debility. Among the acquired diseases the most important in the early days of life were the acute infections, including gonococcus, opthalmia, and vaginitis, the former of which would be entirely prevented if physicians were as careful about instilling nitrate of silver as all midwifes were required by law to be on penalty of losing their licenses. Erysipelas was not frequent, but was peculiarly fatal in young babies. Tetanus was formidable, but less so since the antitoxin was used intraspinously. Sepsis in infants might be caused by a great variety of germs; the infant might be born septic or might become infected through aspiration of infected liquor amnii. The umbilical cord was the most frequent port of entry for sepsis, and next in frequency was the skin. Sepsis in the newborn occurred in many forms; some cases ran their course without symptoms or with only a little fever; others showed signs of suppurative pylophlebitis, acute gastrointestinal disease, or of pneumonia, especially bronchopneumonia. Other patients showed the symptoms of meningitis, and still others were cases of hemorrhagic disease with or without a combination of the meningeal, pulmonary, or intestinal symptoms. Occasionally sepsis affected the joints, bones, or the tissues near the joints. In the treatment of sepsis prophylactic measures were the best. The most promising treatment was either transfusion or the injection of normal blood or serum. In order to better emphasize the clinical significance of some of the injuries and diseases already mentioned, Dr. LaFétra discussed more fully certain symptoms, namely, cyanosis, convulsions, hemorrhage, and vomiting. He stated that convulsions and cyanosis occurred in many of the same conditions. They might arise from intracranial hemorrhage, due to birth injuries or to sepsis, it being difficult to separate the two causes, but in the cases due to sepsis the symptoms came on several days or weeks after birth instead of at once. Both hemorrhagic disease and hemophilia were now treated by the injection of human blood or blood serum, obtained from some member of the patient's family, or if this was not available, diphtheria antitoxin had been very satisfactorily used in many cases. The use of the whole blood was more convenient and could be employed with less loss of time, according to the suggestion of Dr. Oscar M. Schloss, who used from 10 to 30 c.c. every four to eight hours as long as the hemorrhage continued. He had not had any bad results. Dr. LaFétra said he had had excellent results in several cases at Bellevue Hospital, not only of hemorrhagic disease but of general debility and sepsis, with the use of blood or blood serum. The modern treatment of hemorrhages when due to syphilis was the injection of salvarsan or neosalvarsan intravenously together with the use of inunctions of mercury combined with the injection of blood or blood serum. Many a life was now saved by these procedures which formerly would surely have been lost. In considering the significance of vomiting, the writer said that occasional vomiting was met with in all infants whether they were nursed or bottle fed, but there was a type of vomiting which was persistent and not controlled by any simple measure. He then described the projectile vomiting characteristic of pyloric stenosis, and stated that the important signs in the diagnosis of this condition were projectile vomiting without evidences of indigestion, visible peristalsis, and palpable pylorus. In addition to these symptoms, obstinate constipation and the finding of food remains in the stomach several hours after feeding were important. The *x*-ray after the bismuth meal might show the stenosis beautifully. Since at the onset it was impossible to distinguish between hypertrophy combined with spasm of the pylorus and spasm alone, the aim of conservative treatment must be to prevent all irritation of the pyloric end of the stomach by food remains or acid products of gastric digestion. In addition to dietetic measures, treatment should be directed to removing acid mucus, to rendering the pylorus less sensitive, and to relaxing whatever spasm was present. Dr. La Fétra said his personal experience with pyloric stenosis comprised eighteen cases. These could be divided into two groups: First, those in which the spasm was the prominent feature, and, second, those that had spasm and hypertrophy in which the hypertrophy either was or became the most prominent feature. Of the cases with spasm alone, or spasm with some hypertrophy, there were ten; all of these except one recovered without operation. In two of these cases operation was advised by other consultants because of the marked peristaltic waves, and the hard spool representing the pylorus. Five years had elapsed with one of these patients and four with the other, and the children were in perfect health. The patient that died had severe spasm with marked peristaltic waves, but no tumor and necropsy showed a normal pylorus. Of the cases in which the hypertrophy was the prominent feature, seven were operated upon and six died; the other patient died while the surgeon was deciding whether the case needed operation. In the writer's opinion operation was absolutely indicated as offering the only hope of recovery in all cases in which hypertrophy was the prominent feature. The most important indications for operation were progressive loss in weight together with the absence of food residue in the stools. The after care of operated cases was extremely important, careful feeding, extreme quiet and the employment of the Murphy Drip being of extreme importance.

Observations on Conditions in the Newborn, with Special Reference to the Comparative Value in Methods of Treating the Umbilical Stump.—Dr. John O. Polak of Brooklyn read this paper. He said that to be ac-

cepted as satisfactory any method of treating the navel cord must show improved morbidity records on the following points: (1) The temperature of the child during the desiccation period; (2) the degree of icterus and the time of its disappearance; (3) the day on which the slough separates; (4) the condition of the stump after separation; (5) the frequency with which hernia followed, and, finally, the influence which the particular method had upon the body weight of the fetus. At the Long Island College Hospital, during the past five years he and his associates, Dr. Beck and Dr. Hefter, had given four methods a trial and had kept careful records of their results. In their first series they cut the cord at a distance of seven or eight centimeters from the umbilicus, tied it near its distal end and then turned the cord over and tied it a second time, proximal to the first ligature, with the ends of the one placed at the distal end. The loop of the cord thus made, after being wrapped in gauze soaked in alcohol, was laid over the left side of the infant's abdomen, and a bellyband sewed on. Later they had employed the single ligature of the cord. After stripping the cord of Wharton's jelly, a ligature of narrow tape was applied at a distance of two and one-half centimeters from the navel. The sterile dressing was applied as in the first series. Later they had employed a method suggested by Dr. Dickinson which consisted in clamping the cord at birth and wrapping it in sterile gauze until the obstetrician had cared for the mother. Then donning fresh gloves the operator made an incision through the amniotic covering at the skin margin. The vessels were then isolated and ligated with iodized catgut. The cord was then cut away distal to the ligature, the vessels allowed to retract, and the skin margin closed with sutures. A sterile dressing completed the operation, after which the binder was sewn on. This method was ideal as a surgical procedure, but opened up too many possibilities to trust to an interne for its performance. Since last June Dr. Polak said they had modified this method in the following way: The cord was clamped at birth, and with forceps attached and wrapped in sterile gauze, the child was put aside while the mother was cared for. Then with sterile gloved hands the cord was stripped of its jelly, and a fine nosed Kelly clamp was placed on the cord at the amniotic junction, after first being assured of the absence of any navel cord hernia. This clamp compressed the cord, expressed the Wharton's jelly from the area to be ligated and gently crushed the vessels. When the forceps were removed an iodized catgut ligature was firmly tied in the crease thus made and the cord cut away with a knife just distal to the ligated vessels. The sterile dressing and binder were applied as in the previous methods. This dressing was not disturbed until it became soiled, when it was replaced by a similar one. Dr. Polak said the comparative table presented comprised data with reference to 176 cases treated by this new method and 125 treated by the old one. These data showed that the latter method gave as good results as that of Dr. Dickinson. In 176 cases the cord dropped off between the third and fifth day, there was no sloughing mass, or excessive granulations; as compared with 21 cases in the series of 125 by the old method, infection had been absent, icterus markedly diminished, and the regain of the birth weight had been uniformly more rapid than when a large mass of navel string had been allowed to slough. Theoretically there should be fewer hernia as the umbilical opening was not kept patent by a mass of granulating tissue. Since the mouth was another avenue of infection and the epithelium the infant's sole protection against infection we should guard against its injury by the over-diligent nurse who attempted to cleanse the mouth of mucus with a gauze covered finger. The primary inspired mucus might be gotten rid of by inversion of the child, and stroking of the thorax and neck from the abdomen toward the head, or by aspiration with a catheter. For nearly two years they had discarded the practice of washing the baby's mouth before and after nursing, depending wholly upon a sterile nipple to safeguard both mother and child from infection. As a result of this there had been a marked diminution in the occurrence of thrush. In speaking of hemophilia, Dr. Polak said that they had found that the daily examination of the infant's stools by their resident had enabled them to find the first signs of blood, and they felt that not a few babies' lives had been saved by this daily inspection. With the first appearance of blood whole blood from the mother was given subcutaneously into the child, preferably in the region of the back. In severe cases of hemorrhage they had found that a combination of mother's blood, subcutaneously, in 10 c.c. doses, three or four times daily, with transfusion of the infant, injecting the blood through the anterior fontanel into the longitudinal sinus had been life-saving.

Care and Feeding During the First Month.—Dr. GODFREY R. PISEK presented this paper. He said that it would be conceded that the first month in the infant's life was the most important from the standpoint of care and feeding. It was shown by the latest available statistics for the first month of life in Greater New York, that for the first eleven weeks of 1916 the deaths under one month numbered 1,199, against deaths under one year of 2,787; in other words almost 50 per cent. of the deaths occurred in the first month of life. This high mortality could only be lowered by active measures of correction and prevention. Although the attitude of pediatricians had changed considerable during the past five years in the artificial feeding of infants, there was a unanimity of opinion that breast milk was the infant's birthright which it should not be denied. Infants were still removed from the breast by physician or nurse for insufficient reasons, despite the fact that 85 per cent. of all infantile deaths were those artificially fed. The modern mother was usually not ignorant of the advantages of breast feeding and was usually eager to cooperate in preserving the supply. By the addition of one or at most two bottles a day the supply could be kept up and at the the same time allow a period of freedom for the mother. Dr. Pisek said his private case book showed that 30 per cent. of the babies received their mother's milk only; 48.8 per cent. were on the bottle and breast, and 22.5 per cent. were receiving the bottle exclusively. While these figures might vary somewhat in different localities, they showed that breast feeding was on the increase among those who had been accused of shirking their responsibilities. It was a mistake to remove the baby from the breast because milk had not appeared in forty-eight or seventy-two hours after birth, or because there was some vomiting after birth, or because of one hasty or inaccurate examination of the milk, or because the mother or attendants "*think* the breast milk does not agree." Every effort should be made to enable the infant to have the breast alone or at least part breast feeding during the first month of life, for, while the infant might appear to do well for a week or ten days on a formula, its resistance then broke down and its digestion became sadly disturbed and was difficult to correct. Complete emptying of the breasts was the best way of securing a good supply of milk. If artificial milk must be supplied it should not be in the form of rich top milk mixtures, but rather a weak formula, low in fats and proteins, although high in sugar. Only after it was certain that the infant had adapted itself to cow's milk should the strength be increased in the other elements. The healthy new-born infant could be trained to take the breast at four-hour intervals, but this was not the natural interval, the three-hour interval being preferable. In order to determine in questionable cases just how much milk the infant was receiving, it should be weighed before and after nursing throughout one whole day at least. The *x*-ray had shown conclusively that babies could take an amount of milk far in excess of their rated gastric capacity because the milk tended to pass at once into the duodenum. Mixed feeding should not be introduced during the first month if it could be avoided since greater resistance was obtained after a month or two on the breast alone. More than one or two bottles a day were likely to diminish rather than to increase the milk supply, because the breasts would not be thoroughly emptied. If it had been satisfactorily determined that the secretion was constantly deficient, then a bottle feeding should follow each nursing period. If circumstances demanded artificial feeding during the first month of life the physician must recognize the importance of the problem, since one mistake at this precarious period might endanger the life of the infant. The new born infant should not be given such an amount of food as would produce a gain in weight; the caloric requirements were not to be fulfilled until the end of the second week. Boiling the milk during these first weeks was often necessary in order to prevent the formation of tough curds. All were agreed that the cleanest and most wholesome milk obtainable was *the* suitable milk for infant feeding. The treatment of such milk would depend upon the necessity of preserving it, or its modification by a degree of heat which would so alter its properties as to meet the demands of the individual infant. The amount of food allowed would depend on the period selected and should be calculated on a twenty-four hour basis. A baby during its first week would

take ten to twelve ounces daily; in its second and third week from twelve to sixteen ounces; and when a month old twenty ounces. Proprietary foods were often seemingly successful, particularly when of the carbohydrate variety, because of the large amount of dextrimaltose which they contained, or because of their colloidal action on milk, but it should be remembered that giving an infant some sort of food that would be retained and cause a gain in weight was not necessarily good infant feeding. The food must contain enough protein and mineral matter to repair waste and produce new tissue, and enough fats and carbohydrates to supply energy. At no time was it as necessary to inculcate regularity of habits and to abide by the laws of hygiene as in the first month of the baby's life. The obstetrician and the pediatrician must join hands, for on them devolved in a large measure the responsibility of reducing the mortality of the new born.

Remarks on the Occurrence of Syphilis in the Mother.—Dr. J. R. Losee read this paper in which he referred to the many theories on the transmission of syphilis from the parents to the offspring, but said that for the present it was necessary to reason from the history and the clinical findings. There was no definite means by which a parent subject to latent syphilis could be assured that all his children would be born free from any manifestations of the disease. The theory that the spermatic fluid affected the ovum which went on to the development of a fetus, which in turn affected the mother seemed hardly possible. The maternal theory according to which the mother was infected primarily and the fetus secondarily was quite probable and very easy to explain. As most of the still-births from syphilis took place in the latter months of pregnancy, it was fair to assume that the fetus was infected from the mother through the placenta, but whether the placenta could transmit spirochetes without showing pathological evidence of it was an unanswered question. A consideration of the effect of syphilis on the offspring included both the transmission of the infection in its active form, or the transmission of the latent form of the disease. Comparatively few infants born of syphilitic parents went through life without at some time presenting symptoms of the disease. Maternal syphilis had always been considered to play a considerable part in the etiology of abortions, macerated fetuses, premature births, and still births, but it was fair to assume that the same etiological factors were present which had been said to cause abortions in nonspecific women. Intrauterine death of the fetus from the sixth month to term had long been known to be due in most instances to syphilis, and 35 to 40 per cent. of still-born children were due to syphilis. In the past year, of twenty-seven women who were delivered of macerated fetuses at the Lying-In Hospital, nine gave a positive Wassermann reaction. Syphilis had been held responsible many times for the intrapartum death of the infant, but the mechanical conditions which sometimes occurred during delivery and which caused asphyxia would have to be excluded before syphilis could be regarded as the sole etiological factor. Boardman said that two-thirds of all syphilitic children were born about the eighth month; at the Lying-In Hospital in a series of 106 mothers with positive Wassermann reactions, there were thirty-one living babies delivered at term; this might appear a rather large proportion of syphilitic children to reach term, but some of the mothers had received antiluetic treatment during the last three months of gestation. Only about 28 per cent, of the children born syphilitic survived the first year. The Wassermann reaction was valuable in making a diagnosis in doubtful cases, and a four plus reaction meant but one thing. There had been many negative reactions in infants whose syphilitic mothers had received considerable treatment. The spirochetes might be sufficient in number and virulence to produce symptoms in the infant and at the same time not produce enough anti-bodies in the blood serum of the mother to give a positive Wassermann reaction. Judging from the Wassermann reaction, syphilis had little or no part in the etiology of fetal anomalies. At the Lying-In Hospital, during the past two years the sera of 2,049 patients were examined, and sixty-four, or 3.05 per cent. gave a positive Wassermann reaction. This gave one a fair conception of the extent of the disease among women at the child-bearing age in the lower east side of the city. The result of the antiluetic treatment of pregnant women, estimated by the number of children born with or without symptoms, depended on the amount of treatment the patient received during pregnancy. It was believed that salvarsan could be given in moderate doses at intervals of a few days, without danger to the fetus and without inciting premature labor, but large doses were dangerous. There was considerable difference of opinion as to whether salvarsan given intravenously to the mother was transmitted to the fetus. Of ten cases treated during pregnancy, five received arsenic and mercury from the second month to term; three gave birth to living babies without symptoms and with a negative Wassermann reaction; one who was in the active secondary stage throughout her pregnancy was delivered of a living baby without symptoms, but with a positive Wassermann, and one was delivered of a macerated fetus at seven months. Of the five cases which received treatment from the seventh month to term, five living babies were delivered and three gave positive Wassermann reactions.

Dr. Henry Koplik said that in a large metropolitan city like New York it was astonishing how little was done for the new-born infant in the maternity hospitals, especially in view of the vast sums of money that had been put into these institutions and the fact that no facility had been omitted that would contribute to the care of the mother; yet very secondary care was given the infant. He had seen a considerable number of infants in one small room tucked against the side of the wall in structures something like waste baskets. He had also seen ten or twelve babies cared for by a single nurse who was expected to care for all the wants of all these infants. Fully 30 per cent. of the infants below three months of age died during the first month of life, so that it was highly important to give attention to the infants in these hospitals. There was little excuse for sepsis in a modern hospital, yet Dr. Koplik said he would blush to tell how many cases of sepis he had seen in these institutions. Again there was little excuse for artificial feeding in a modern hospital. It was painful to see the large number of babies on the bottle. It seemed that if the mother was unable to nurse her baby mother's milk could be obtained from other sources. In many hospitals they still relied upon primitive methods in dealing with hemorrhage and melena. On finding the first traces of blood the first thing to do was not merely to stop the bleeding but to place the child in such a condition of resistance that he might be able to combat other troubles. In addition to more room and better facilities for the care of the new-born in our hospitals, the staffs of maternity hospitals should have special physicians to take charge of the new born and to give these babies the benefits of modern progress in pediatrics. A great deal had been said with reference to prenatal care, but Dr. Koplik said that, in his opinion, not much could be done in this direction unless they could obtain the cooperation of the fathers as well as that of the mothers. The father must appreciate the necessity of these things and more could be done by getting the cooperation of the whole family than by simply trying to care for the mother and the unborn infant alone.

Dr. Edwin B. Cragin said that as obstetrician he would acknowledge that they were under great obligations to the pediatrist, but he would also like to call attention to the fact that if it were not for the skill of the obstetrician the pediatrist would not have so many babies to care for, so that it seemed to him that the pediatrist was also under great obligations to the obstetrician. To judge from the first paper it would seem that the obstetrician was unfit to care for the baby during the first month, but if the obstetrician had eyes and ears and was a keen observer, if he watched the woman carefully through her pregnancy, if he had the opportunity of studying from fifteen to eighteen hundred babies a year, and was any sort of a man, he must learn quite a little about the care and feeding of the new-born infant. If Dr. Koplik had made the rounds of these maternity hospitals he would have found that the babies were given due consideration and he would have found that even the "waste baskets" on the walls had their advantages, since they could be taken off the walls when the beds were to be made or could be separated to avoid infection of one baby from another. The properly trained obstetrician should not be regarded as an incompetent care-taker of a baby during the first month. Many women, much to their regret, could not nurse their babies. At the Sloane Maternity they could not get breast milk enough. Whether because of the nervous strain and high tension of modern life, or whatever the cause, the fact remained that fewer mothers were able to nurse their babies than ten years ago. Breast milk was difficult to buy and what could be bought was usually taken for private patients.

Dr. POLAK spoke of having dispensed with the habit of swabbing babies' mouths. For a number of years they had not allowed the nurses to swab the babies' mouths either in the delivery room or before or after nursing. Less than a month ago the head nurse complained that they were having more cases of thrush than they ought to have and they were now allowing the nurse to cleanse the mouths of the babies with sterile cotton and boric solution once a day at the time of the bath. This was simply an instance of one of the practices which we discard and then go back to later on. The duty of the obstetrical hospital today was to get the mothers early and surround them with every possible care. A Wassermann test should be made in the case of every patient early in the course of pregnancy both for the welfare of the mother and for that of the baby. Moreover it was of great interest to the hospital because a baby apparently healthy at birth might be sent out of the hospital and then given to a foster mother and give that foster mother syphilis; hence the making of a Wassermann test was extremely important. Having followed the woman during her pregnancy, and having seen her safely through the puerperium, it was then their duty to put the mother and baby in touch with the proper welfare agency or pediatrician, so that proper care might be insured after the baby left the institution.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

OBSTETRICS, NORMAL AND OPERATIVE. By GEORGE PEASLEE SHEARS, B.S., M.D. Published by J. B. Lippincott Company, Philadelphia and London. Illustrated. Price, $6.00.

BURDETT'S HOSPITALS AND CHARITIES, 1916. The year book of philanthropy and hospital annual. By SIR HENRY BURDETT, K.C.B., K.C.V.O., twenty-seventh year. Published by the Scientific Press, Ltd., 28 and 29 Southampton St., Strand, W. C. Price $2.00.

TEXT-BOOK OF PHYSICS AND CHEMISTRY FOR NURSES. By A. R. BLISS, JR., Ph.G., Ph.C., A.M., Phm.D., M.D., and A. H. OLIVE, A.B., A.M., PhC., Phm.D. Published by J. B. Lippincott Co., Philadelphia and London 49 illustrations. 239 pages. Price, $1.50 net.

SURGICAL AND GYNAECOLOGICAL NURSING. By EDWARD MASON PARKER, M.D., F.A.C.S., and SCOTT DUDLEY BRECKINRIDGE, M.D., F.A.C.S. Published by J. B. Lippincott Co., Philadelphia and London, with 134 illustrations in text. 425 pages. Price, $2.50 net.

METROPOLITAN WATER AND SEWERAGE BOARD. Fifteenth annual report for the year 1915. Published by Wright & Potter Printing Co., State Printers, 32 Derne St., Boston, 1916. Public Document No. 57. 224 pages.

HOSPITAL LABORATORY METHODS FOR STUDENTS, TECHNICIANS AND CLINICIANS. By FRANK A. MCJUNKIN, A.M., M.D. Published by P. Blakiston's Son & Co., 1012 Walnut St., Philadelphia. One colored plate and ninety-three illustrations in text. 139 pages. Price, $1.25 net.

CATARRHAL AND SUPPURATIVE DISEASES OF THE ACCESSORY SINUSES OF THE NOSE. By ROSS HALL SKILLERN, M.D. Published by J. B. Lippincott Co., Philadelphia and London. Second edition, thoroughly revised, with 287 illustrations. 417 pages.

THE CLINICS OF JOHN B. MURPHY, M.D., AT MERCY HOSPITAL, CHICAGO. Edited by J. G. SKILLERN, JR., M.D., of Philadelphia. Published bi-monthly by W. B. Saunders Co., Philadelphia and London. June, 1916. Vol. 5, No. 3. Illustrated. 549 pages. Price, $8.00 per year; foreign, 35 shillings.

STUDIES FROM ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH. Reprints Vol. XXIII. Published by the Rockefeller Institute for Medical Research. New York, 1916. Illustrated. 506 pages.

SKIN CANCER. By HENRY H. HAZEN, A.B., M.D. Published by C. V. Mosby Co., St. Louis, 1916. Ninety-seven text illustrations and one colored frontispiece. 251 pages. Price, $4.00

THE DREAM PROBLEM. By Dr. A. MAEDER, Zurich. Published by Nervous and Mental Disease Publishing Company, New York. Price, 80 cents.

Miscellany.

The New York State Hospital Commission, in conjunction with the State Charities Aid Association, has recently established a mental clinic in the out-patient department of the Williamsburg Hospital, Brooklyn, under the charge of Dr. E. M. Somers, superintendent of the Long Island State Hospital, and Dr. W. A. Macy, superintendent of the Kings Park State Hospital. There are now three mental clinics in Brooklyn, the others being at the Long Island College Hospital and the Long Island State Hospital, and at all of these free advice and treatment with respect to incipient mental conditions are given with the hope of preventing complete mental breakdown in the patients coming to the clinic. After care among the insane is also a feature at these clinics and social workers are employed.

Infantile Scurvy and Pasteurized Milk.—In the discussion of a paper by Dr. Funk on "Vitamines, a New Factor in Nutrition," at the Academy of Medicine, Dr. L. Emmett Holt expressed the opinion that infantile scurvy was undoubtedly on the increase in this city and that the increase was due to the exclusive use of pasteurized milk in the artificial feeding of infants. That this conclusion is probably correct is indicated by the interesting clinical observation reported by Dr. Alfred Hess at the same meeting. Hess found that a mild grade of scurvy developed in a group of infants artificially fed on pasteurized milk and barley water, while a control group, to whose diet orange juice was added, but who otherwise received the same milk modifications as the first group, remained entirely free from scurvy.

Among the infants in the first group the scorbutic symptoms promptly disappeared on the administration of orange juice.

Most of the cases of infantile scurvy now being encountered are of a milk type; so mild, in fact, that many of them escape recognition even at the hands of experienced physicians. On the other hand, the dangers of milk-borne disease are real, and constantly carry with them a grave menace to life through tuberculosis, typhoid fever, septic sore throat and other infectious diseases. In contrast to this we have a mild grade of scurvy which can readily be prevented or cured by the addition of a little orange juice to the diet. Furthermore, a safe raw milk (guaranteed or certified) is available for those cases in which pasteurized milk even with the addition of ample antiscorbutics does not meet the requirements. Such cases must be extremely rare.

Instructions have been given by the Department of Health to the physicians and nurses in charge of its milk stations and of the baby welfare work in the homes to be on the alert for any of the early signs of scurvy and to insist upon the use of orange juice or other suitable antiscorbutics when babies are exclusively bottle-fed on pasteurized milk. While the Department of Health has no intention, therefore, of altering its policy with regard to pasteurization, physicians may rest assured that it likewise does not contemplate or look with favor upon any administration of milk control in any community which eliminates the privilege of securing a safe high-grade raw milk for those whose lives may depend upon its use.—*Weekly Bulletin of the New York City Department of Health.*

SEBORRHOIC DERMATITIS.

By WILLIAM P. CUNNINGHAM, A.M., M.D.,

NEW YORK.

ATTENDING DERMATOLOGIST TO THE MISERICORDIA HOSPITAL.

In my student days we had a ridiculous bit of doggerel which ran about like this: "All I know is Syphilis and Eczema; and I can't tell which from which; except by the fact that Eczema itches and Syphilis does not itch." In our boastful contempt for the science of dermatology we would chant this shameful confession of puerile immaturity and stupid self-sufficiency. We didn't give a straw for dermatology and we gloried in our ignorance. What enthusiast for humanity would waste any of his valuable time in pursuit of such an ignoble object as the relief of itching? There were many loftier ambitions in medicine than that! There were the grave diseases that threatened life to be mastered; there was the magnificent art of surgery beckoning to our mounting souls! Fudge for pimples and pruritus! With a steadfastness worthy of our high ideals we clung to our haughty aloofness and graduated in disdainful darkness on the whole distasteful topic. This most of us retained in our day of early dreaming of the dazzling of the world; and in that later day of disillusionment when during the grind of an active practice we discovered the need but lacked the time to repair our blunder. We soon found that the big things were in the hands of a few men, that the common run of human ills were ours to alleviate. We many times found acne staring us in the face. We were many times embarrassed by our inability to relieve the itch of a patient whose esteem meant much to us. We realized too late that there is an imposing number of complaints disturbing the pride and comfort of the patient that must be attended to as zealously as the graver abnormalities that jeopardize existence. Where itch "hath murdered sleep" the application is obvious. But even the demands of vanity have frequently a substantial basis of economic importance. Socially girls with acne are badly handicapped. They may be overlooked in the matrimonial quest. They are not sought after in business. They often lose excellent opportunities for material and professional advancement. Men, too, with their reputed contempt for the lighter conceits of life are sometimes seriously hampered by the presence of disfiguring eruptions. Aside from their unsightliness, they are needlessly mistaken for contagious conditions and their victims are cruelly avoided. It is superfluous to state that itching dermatoses do not enhance the winning ways of business or social intimates. The person who is given to scratching is looked upon with disapproval and distrust. Such a person will soon face the alternative of quitting the practice or quitting his job. Driven by the double incentive of seeking relief and saving his occupation he will demand instant results at the hands of the doctor. And if the doctor is one of those high-minded scientists with a contemptuous disregard for the little things of life he will find himself facing the alternative of losing a profitable patient or condescending to investigate what he had heretofore despised. In short, he is jolted into his senses by the discovery that, to the patient, this persistent irritation is one of the big things of life: that it is just as essential to his health and happiness to cure him as it is to operate for appendicitis on an enlarged thyroid. The present ill is the biggest ill to the exasperated sufferer and he will not hesitate to assert that he would sooner have a serious condition and be done with it than be an object of suspicion and dislike. Opportunities are seldom vouchsafed the busy practitioner to retrieve his deficiences, and it is almost certain that unless he happens to hit upon the proper treatment by a lucky chance, he will be chagrined by the defection of his patient into other and probably no worthier hands.

The blame for this costly lack of practical knowledge rests squarely upon the shoulders of the faculties of our medical colleges. Students on graduating have some acquaintance with the eye, ear, throat, nose, rectum and generative apparatus, and are capable of delivering at least a glancing blow at the diseases appertaining thereto. But in the matter of the skin their ignorance is proportionate to the apathy of their instructors. Both are the victims of an error of mental refraction whereby the perception of relative values is badly obscured. And yet this defectively equipped practitioner, unless all his time is taken with the demands of his business (when it is obvious he will not feel his lack), may with a little attention learn many useful lessons as it were on the wing, which will serve him profitably on occasion. Familiarity with certain common forms of skin disease is readily acquired and cannot fail to prove a valuable asset. For example, the subject of this paper if properly grasped, will furnish the means of deciphering many otherwise inexplicable conditions.

Seborrhoic dermatitis is frequent. It occurs at all ages. It has well-marked characteristics which are usually in evidence. It has no mysterious internal causation. Its origin is local. It begins upon the scalp. Thence it descends by the scattering of the scales to contiguous and even remote localities. The chief distinguishing feature of a typical case is a greasy scaliness. There is a dermatitis accompanied by an increased flow of the natural cutaneous lubricant—the sebum. This partly dries and thus forms scales or crusts that are unctuous

to the touch. At times the dermatitis predominates and the drying is more complete and the scales are finer and crisper. Beginning as it always does upon the scalp it first produces an annoying oiliness which resists stubbornly all our efforts at control. Soon the hair begins to fall. Later there is an alteration in the exudation and it loses its pronounced greasy character and forms a fine bran-like scale popularly known as dandruff. And still the hair continues to fall. This is the threatening condition for which assistance is oftenest sought. The grease may be combated finally by persistent washings, and the dandruff may be zealously brushed away, but the thinning of the hair excites the gravest apprehension among men as well as women, and they frantically demand its inhibition. This is not prompted solely by vanity but by the dread of the effect of the signs of age upon business opportunities. It is usually maintained that with the advent of maturity depart the vim and push of youth. It is a curious commentary upon the sinuosity of human intellection that the very men who entertain that opinion would be shocked at its application to themselves. In passing it may not be amiss to reflect that the weakness that we contemn under the name of vanity may be in reality only another phase of that struggle for existence, and for the supremacy of the fittest that is so relentless among us. The woman paints her face to extort observation and admiration. She seeks the glances of the male. Behind this is more than the childish desire for approval. She is following the world-old impulse of her sex to attract a mate and protector. We concede that she is mistaken in her method, but there is no gainsaying the motive.

The cause of the falling hair is the situation of the disease in the sebaceous glands and the hair follicles. The sebaceous glands open in the neck of the follicles and the hair is destroyed by the inflammatory action and by the alteration in the quantity and consistency of the sebum. It is swamped or choked accordingly as the exudate is profuse and oily or scanty and dry. The follicle is wrecked by the disturbance within it. The struggle is to a finish and the follicle does not "come back." The thinning of the hair is most pronounced upon the vertex, but may be pretty even all over the scalp, especially in women. Some itching is usually associated with the disease; occasionally a great deal. This is the reason for the evocation of that ridiculous hybrid known as "seborrhoic eczema." It may be as well to lay the monster here as elsewhere. There is no such entity as "seborrhoic eczema." Admitting or denying the oneness of eczema with dermatitis there is no question that the disease we are considering is a plain unequivocal dermatitis with a hypersecretion of sebum. It lacks vesiculation and this distinguishes it from that other variety of dermatitis that we designate "eczema." From the scalp the process may extend upon the forehead, behind the ears into the eyebrows and over the face. In these various situations its appearance may be typical, namely, that of reddened patches covered with greasy scales or an intertriginous character may be acquired behind the ears or a dry scaly character upon the cheeks. The skin about the angles of the nose and mouth may present a patchy look with a yellowish tinge and a slight furfuraceous scaling. There is no vesicular oozing. There is very little infiltration. Itching may be moderate. It is rarely troublesome. Circles and loops of various sizes are sometimes noted. Again, in an acute exacerbation the whole countenance may be involved in one red and scaling mask. But there is always the element of greasiness and the absence of vesiculation and thickening. Corroboration may be found in the scalp. Extension may take place to the neck either in patches or by continuity.

On the body the disease is set up by the scales that drop from the scalp, or are carried down by the hands or the drawing of the undershirt over the head. It has a predilection for the sternum axillæ, umbilicus, groins, and interscapular region. In extensive cases it may be almost universal except for the palms and soles. These two localities are never affected. The disease upon the body may be exactly like that upon the head, or owing to the friction of the clothing and opposing surfaces and the retained heat of the covered skin it may present decided variations. Usually the patches are a yellowish red. Often the yellow is only suggested, not actually discernible; a distinction that the French express by the word "nuance." The patches are round, oval, or irregular, but always with a well-defined margin. Scaliness is usual and variable. On the parts exposed to pressure, such as the axilla, the scales may be removed by maceration, on other parts they may be removed by the friction of the clothing; and then we have only the reddened patches clearly outlined, slightly thickened if at all, but free from evidences of vesiculation. Some of the aberrant cases assume fantastic forms, circinate, gyrate, and geographical. If upon examining a patient you find reddish or yellowish lesions in the indicated situations, whether scaly or bare, large or small, and you also find a pityriasis capitis, with or without a thinning thatch, it is reasonably certain that you have to do with seborrhoic dermatitis. "Reasonably certain" is an etymological incoherence because certainty is certainty and there are no degrees thereof. But this mode of expression will be condoned when it is explained that it is employed to convey the idea that convincing as clinical appearances may be there is yet an element of uncertainty in the diagnosis. Unfortunately some phenomena of seborrhoic dermatitis so closely simulate some phenomena of psoriasis that the distinction is often a matter of opinion. These are called border line cases both by the men who believe in their identity and by those who do not. There are authorities who maintain that psoriasis is a dry form of seborrhoic dermatitis and that seborrhoic dermatitis is a greasy form of psoriasis. Others assert that a true psoriasis develops upon the lesions of the simulating malady. A real pathological transmutation has occurred. There are still others and probably the large majority who stoutly insist that the two are entirely distinct even when apparently identical. There have been cases where the doubt has been resolved only by the recurrence of psoriasis in an utterly unmistakable form. The prognosis is entirely different in the two diseases and it is imperative, aside from the academic interest, to get the diagnosis right. You can assure the victim of seborrhoic dermatitis that his disease is curable. To the psoriatic, you can hold out no such hope. Psoriasis will recur with certainty at the change of the seasons, and at periods of mental depression and physical unfitness. The best that can be looked for is the repulse of the attack within a reasonable time after its appearance and the restriction of it to regions that can be con-

cealed. This may be accomplished by arsenic chrysarobin and ammoniated mercury, aided and abetted by a proper modification of diet. Not only in the interest of the patient but in the interest of the physician the distinction between these two conflicting conditions should be clearly drawn because it would be humiliating in the extreme to make a prediction quickly proven to be erroneous. The obstinacy of psoriasis, its persistent recurrences, and its selection of sites avoided by seborrhoic dermatitis will definitely establish the distinction. Psoriasis favors the extensor surfaces of the limbs. The elbows and knees are rarely exempt. The eruption may be scanty and the individual lesions no larger than pin heads, yet these four locations are nearly always involved. It is a diagnostic point of the greatest significance and should be steadily borne in mind. With a sealing eruption so situated psoriasis may be proclaimed and defended with the utmost confidence. On the trunk it is apparently distributed without much choice of locality. It is somewhat rarer in the areas favored by seborrhoic dermatitis, namely, the groins axillæ and umbilicus. It is very rare upon the face. But we should not overlook its occasional appearance in these unusual situations, especially when it involves a great deal of the cutaneous surface. As a general proposition it may be avouched that seborrhoic dermatitis is thicker in the middle line of the chest and back and thins out towards the flanks. Psoriasis reverses this order of progression. It is thicker on the flanks and thins out towards the middle line. This peculiar distribution of seborrhoic dermatitis is accounted for by the method of its communication from the head to the trunk. The scales naturally fall more in the middle line. The contrary course on the part of psoriasis admits of no explanation whatsoever. The character of the scale is offered as a differential point between the two diseases. That of psoriasis is dry and pearly. That of seborrhoic dermatitis is greasy. Even in the so-called seborrhea sicca the scale on being rubbed between the fingers reveals its oily composition. In the border line cases recently mentioned the drying of the scale may have been so complete as to defeat this means of comparison. Another method of demonstrating the significance of the scale is to scratch it with the finger nail. If it peels off without revealing a bleeding point it is not psoriasis. If it does reveal a bleeding point it is psoriasis. The one element of uncertainty in this proceeding is the circumstance that any scaly lesion will bleed if you scratch it hard enough. And unconsciously in our effort to sustain our preconception, we will cheat by a little extra pressure. So this means of differentiation is not to be too confidently relied upon. On the scalp the two conditions are especially liable to be confounded because unless the seborrhoic feature is strongly emphasized, the findings are remarkably alike. The hair if thick conceals the conformation of the psoriasis patches, so that nothing but a more or less dense scaliness is discernible. In seborrhoic dermatitis, however, there will sooner or later be noticeable thinning of the hair. This does not occur in psoriasis. Itching is present in seborrhoic dermatitis and is rather unusual in psoriasis. Considering that the eruption of psoriasis upon the scalp is frequently the thicker and denser of the two, it is curious that itching is absent and that the hair does not fall. The explanation of the hair loss in seborrhoic dermatitis lies undoubtedly in the relation between the seborrhoic gland and the neck of the hair follicle. The gland opens into the neck of the follicle. Involved in the inflammatory process at its very root the hair is choked to death. The pressure of the denser psoriasis patch should, in the very nature of things, be heavier and if that factor alone were sufficient to destroy the hair, baldness would be a constant consequence. A simile might be found in the heavy mantle of snow that does no damage to the underlying vegetation and the cloudless frost that penetrates to the heart of the struggling root and nips its life out. It is true that seborrhoic dermatitis is observable at every period of life, but it is naturally commoner after the fuller development of the sebaceous glands at puberty. Many cases occur in children. It has been seen in a most aggravated form in a child three weeks old; its head entirely bald and a well-defined crusted eruption at the nape of the neck, under the nose, on the chin, behind the ears, in the axillæ, in the groins on the scrotum, and covering the buttocks and back of the legs clear down to the heels. Another case was observed in a child of seven, where the scalp was covered with a heavy crust of the color of sulphur. The eyebrows and ears were slightly affected. A diagnosis of "regular eczema" was sought to be established because owing to the activity of the dermatitis there was a little oozing. An inspection of the body, however, revealed a typical seborrhoic dermatitis. It has been shown that much of the infantile eczema is of this character, especially when it involves the umbilical and genital regions.

The differentiation has sometimes to be made between this condition and orbicular eczema. Orbicular eczema is a circular or oval patch, arising abruptly from the surrounding skin, presenting when frequent many of the features of vesicular eczema, but clearly of so distinct an individuality that its proper classification has yet to be determined. When chronic these patches become scaly and then the resemblance to seborrhoic dermatitis is quite marked. The distinction rests upon the minor degree of infiltration and itching and the contemporaneous involvement of the scalp, in the seborrhoic manifestation. Sometimes it rests upon the reputation of the eminent man who makes it.

Ringworm of the face or body has been confused with the circinate eruption of seborrhoic dermatitis. Ringworm shows more pronounced central clearing with a decidedly elevated edge, studded with vesicles and pustules. It would be rare indeed for seborrhoic dermatitis to be limited to a single lesion whereas that is the rule in ringworm. Where multiple ringworm invades the face or body of an adult the confusion may be troublesome for a time. Close scrutiny will relieve it. Ringworm of the crotch, absurdly designated "eczema marginatum," is occasionally a source of perplexity because it occupies one of the classical situations of seborrhoic dermatitis. A sharply defined and distinctly elevated border, with central clearing or at any rate central paling, indicates the disassociation. A scraping examined under the microscope will be conclusive.

Pityriasis rosea has been paradiagnosed seborrhoic dermatitis and *vice versa*. Parenthetically it may be explained that a "paradiagnosis" is a nearly correct incorrect diagnosis. Etymologically constructed on the order of "paraphrase," "parallel," "paraclete," and "paratyphoid," it suggests something resembling something else. It is a diagnosis that just misses its aim. It is a "para" or "near"

diagnosis. It bids fair to be a handy word saving the frequent employment of a phrase.

To come back to pityriasis rosea; if its peculiarities are distinctly recalled, a correct opinion can always be pronounced. The outline of typical pityriasis rosea would roughly conform to that of a bay leaf. Its tint is pinkish or pale red with a hint of yellow. The surface is slightly scaly. It has been compared to cigarette paper because of the delicate crinkling it displays. A peculiarity often noticed is the curling up of the epidermis into a little cuff between the pinkish periphery and the fawn-colored central portion. You may support your diagnosis against any amount of adverse argument if you discover that sufficing sign. Even in cases that have been badly treated and in which the original color and outline have become obscured, you may by diligent search be able to find the little cuff and establish the diagnosis. Frankly, pityriasis rosea is a trivial affection, noteworthy only because of its euphonious title, its persistence under misdirected treatment and the doubt it creates in the mind of the apprehensive patient. The treatment for seborrhoic dermatitis will not touch it so it is important to make the differentiation.

Intertrigo is a dermatosis that appears in localities favored by seborrhoic dermatitis; the axillæ, the groins, the mammary folds, and the retroauricular cleft. Circumscribed, inflammation thus confined is immediately attributed to the friction of the parts and the case is regarded as etiologically disposed of. Aside from the fact that in undoubted intertrigo something more is involved than mere heat and friction (else intertrigo would be universal); it is curious that it is frequently counterfeited by seborrhoic dermatitis. Much of the accepted infantile eczema about the genitals is seborrhoic. In tissues folded on themselves maceration is certain to complicate any eruption. Hence the two conditions bear a strong likeness to each other. But in the seborrhoic condition will be found outlying spots where there is no overlapping adjustment, and these establish the correct diagnosis.

The ordinary, commonplace "eczemas" offer evidence of present or preceding vesiculation and infiltration, and pruritus is obtrusive as a rule. "By these signs ye shall know them." But one variety of "eczema"—the erythematous—wherein vesiculation is so slight that it is entirely hypodermic, and discernible only to the marvelous vision of the expert dermatologist, may be and in point of fact frequently is mistaken for seborrhoic dermatitis, or *vice versa*. This confusion is commoner on the face than on the trunk and limbs, for on the face the scales of seborrhoic dermatitis are apt to be drier and less unctuous owing to the action of the air and frequent ablutions. It is also disposed in patches unless it happens to be very extensive.

It favors the eyebrows, the angles of the nose and mouth, and the retroauricular space. It is always associated with pityriasis capitis. Lupus erythematosus is frequently overlooked under the impression that we have to do with seborrhoic dermatitis. At a certain stage of the graver condition the resemblance is striking. One of the older titles of lupus erythematosus based on its alleged etiology, was seborrhea congestiva. If the older pathologists believed that one led to the other the distinction must oftentimes be extremely difficult. The lupus give the evidence of deeper invasion, its scales are scanty and very adherent, and—a sign that settles the question beyond all peradventure—there is atrophy demonstrable here and there throughout the lesion. Lupus erythematosus is regarded to-day by many acute observers as a tuberculide. *That* is a disease produced by the toxins of the bacilli and not by the bacilli themselves. Its prognosis is vastly different from that of seborrhoic dermatitis. Be especially circumspect in expressing an opinion about lesions on the scalp and on the helix and in the concha of the ear. Both diseases affect these regions. Make a careful search for atrophic areas before coming to a conclusion.

The causation of seborrhoic dermatitis is sub judice. There are those who believe they know and those who admit they do not. Sabouraud offers his microbacillus. Unna offers his morococcus. Others postulate a nervous origin. Stelwagon lays stress upon constitutional causes as predisposing, but declares that the essential pathogenic factor must be considered parasitic. In point of fact, nothing is settled upon the question of etiology. The parasitic origin is supported by the fact that the eruption is scaly, begins on the scalp, has a tendency to take the circinate form and is controlled by parasiticides.

Transmission by autoinoculation lends additional plausibility to this view. But even the most earnest advocates thereof qualify their opinion by urging attention to systemic conditions on the ground that vulnerability to the parasite is increased by lowered vitality from any cause whatsoever.

Before leaving this topic it may not be unfruitful to repeat the declaration of Sebouraud that acne and acne rosacea are consequences of seborrhea and that they will never be cured until the latter is controlled. This is introduced for what it is worth.

Seborrhoic dermatitis is quite amenable to treatment except upon the scalp, where it is difficult to make effective applications on account of the hair. On the body ointments of sulphur, resorcin or ammoniated mercury, singly or in combination, are usually successful. Our results upon the body are in sharp contrast to those upon the scalp. This is the more regrettable because it is the ravages in the later situation that are costly and disfiguring. On the non-hairy surface the lesions may be hidden unless the face is involved. And even in the latter contingency prompt response to treatment may be anticipated. But upon the scalp the disease presents two exasperating features. It destroys the hair and stubbornly resists the efforts made to cure it. The destruction of the hair is disconcerting to both man and woman, for reasons that are perfectly obvious. The woman foresees the loss of her attractiveness; the man foresees the aspersion of waning efficiency. The former has methods of concealing the depletion; the latter rears his glistening pate in impotent despair. He is the subject of stupid raillery upon the traditional but undoubtedly apochryphal fondness of baldheaded men for advanced positions at spectacular theatrical performances. What association there can possibly be between waning hair and waxing sensuality has never been explained. It is probably nothing but a wicked invention of the professional humorist. These considerations are weighty enough to stimulate the doctor to earnest cooperation with the apprenhensive patient for the preservation of his locks. What are the best means of accomplishing this laudable purpose? As the mill will never grind again with the water that has passed, so the scalp will never bloom again with the hair that has departed. Once it has fallen out, under the blight of seborrhea, we may

bid it a fond farewell. Much may be done, however, to stay the devastation and tenderly nurture that which is left. On the scalp lotions are preferable to salves, because of the aversion to greasy heads in most civilized assemblages. It is fair to admit that the results leave much to be desired. Factors responsible for this are the complicity of accumulating years in the attenuating process; and the disinclination of the average patient to make an uphill fight in the face of trivial encouragement. But persistence will win here as in any other field of human endeavor, if it is intelligently guided. Lotions should be applied with a medicine dropper directly to the scalp and rubbed in gently but steadily for about fifteen minutes. Energetic action will precipitate the falling of those hairs already loosened by the disease. Washing the head should be restricted to the demands of decency. It should not be undertaken under the delusion of assisting the cure, for water is decidedly objectionable, unless properly medicated. On these rare occasions a good brand of tar soap should be used. The lotion most in vogue is composed of resorcin 10 per cent. in alcohol and water. Glycerin may be added if the hair is dry. The proportions of alcohol and water may be varied to suit individual requirements. If the resorcin proves unsatisfactory bichloride of mercury may be substituted in the same menstruum. One grain to the ounce will be a fair average strength. If another essay is demanded a 1 per cent. solution of lysol is helpful. It has the disadvantage of being malodorous. This may be mitigated by oil of bergamot. If lysol prove offensive or inefficacious betanaphthol 2 per cent. in alcohol and water is worth a reasonable trial. Some cases will not yield to lotions and in order to stay the falling hair recourse must be had to the ointment of ammoniated mercury 5 per cent. It will not be prudent to exceed that proportion. It is to be applied only at night, and the hair may be wiped off with a towel in the morning.

The changes may be rung on the remedies, and sulphur may be cautiously combined. But this sums up the profitable procedures in any case of seborrhea. In these days of bold experimentation the *x*-ray was certain to be turned upon the scalp for the relief of this alarming denudation. It may be affirmed in all fairness that it offers no better prospects than the chemical applications; if it is used with discretion and restraint. If pushed beyond the bounds of prudence it will cause a complete alopecia, which may or may not be permanent, and which may be followed perhaps after a lapse of several years by all the disfigurement and hazard of an *x*-ray burn. It is "better to bear those ills we have than fly to others that we know not of."

616 Madison Avenue.

Preeclamptic Toxemia.—J. O. Arnold states that this condition should be treated as promptly and actively as eclampsia itself; that morphine in sufficient quantity is the safest and most effective agent for temporarily controlling convulsions; that vivisection, early and freely, is the quickest and best means for securing elimination and reducing blood pressure; that the high degree of acidosis in eclampsia calls for alkali-salt solution to replace the toxic blood withdrawn; that in practically all cases, after controlling the convulsions, the second step in treatment is to empty the uterus. By prëeclampsia the author means impending eclampsia, the case seen at the time of the first convulsion.—*Therapeutic Gazette.*

IS INFANT MORTALITY AN INDEX TO SOCIAL WELFARE? SCANDINAVIA'S REPLY.

By KATE C. MEAD, M.D.,

MIDDLETOWN, CONN.

Sir Arthur Newsholme, the eminent English statistician, says that infant mortality is the most sensitive index we possess of social welfare. And then he adds: "If babies were well born and well cared for, their mortality would be negligible. The infant death-rate measures the intelligence, health, and right living of fathers and mothers, the standards of morality and sanitation of communities and governments, the efficiency of physicians, nurses, health officers, and educators."—Bulletin of the Chicago School of Sanitary Instruction.

This quotation, though of recent date, applies not only to the unenlightened families of the twentieth century, but to the most highly educated classes of past ages. Being well-born and well-cared-for are relative terms, and if we to-day who are well-born can use our brains and our funds in caring for the ignorant the time may come when all babies will have as good a chance to live as seems to fall to the lot of the babies of the educated classes at present.[1] Two hundred years ago the babies even of the nobility in Europe were seldom well-born or well-cared for. Queen Anne of England who died in 1714 at the age of sixty-nine, bore fourteen children, only one of whom lived more than a few hours or weeks, and the one survivor, upon whom the fate of the nation seemed to hang, died before he was eleven years old. That the early deaths of these royal infants was an index of the lack of general intelligence of that age is shown in the general debased state of morals and religion. The recorded conversation at social functions ran upon preserving the English Constitution, but not at all on saving the constitution of babies, although one-sixth of all English infants died of sepsis, and half of the rest died of what we now class as preventable diseases. This high mortality was common to all enlightened countries even fifty years ago, but gradually it has been lowered until now, in the United States, only 15 per cent. of the babies die in their first year, a decrease which seems commendable when we find that, though we are eighteenth in a list of the infant mortality of different countries, Italy has a rate of 16 per cent., Germany 19, Austria 22 and Russia 26. But why should we be content before we have reduced our death rate to that of Sweden in the first rank, with its infant mortality of only 7½ per cent.?

This question leads us to look into our municipal housekeeping, where, as Sherman H. Kingsley has shown, the weakest spot is continually marked by the presence of the little white hearse, the most sensitive index to the enlightenment of any community being its infant mortality. Or, as Holt has pointed out, it is not the unfit, but the unfortunate; baby that dies, and this baby who was born in the midst of poverty or unenlightenment dies or grows up sickly in its home, or perishes sooner in a foundling asylum. These early deaths in any case, then, are the index to our poor economies in municipal housekeeping.

That the death rate of infants in foundling asylums is enormous may be seen from statistics quoted by Dr. Philip Van Ingen, who finds that the rate in New York State's foundling homes is 422 to the thousand, while the death rate of the babies in the

slums of New York City is hardly more than one-fifth of that number. That the deaths in these foundling homes are mostly unnecessary is seen by comparison with the death rate of foundlings in Sweden, which is only 4 per cent., but we shall see that there are good reasons for this difference. Sweden has not only hospitals for sick babies, but small boarding homes for well babies, and large asylums for mothers with their babies. By such methods New York City has cut down its infant deaths 17 per cent. in the past five years, that is, by boarding 44 per cent. of its foundling babies in small homes where each individual may have a mother's attention, under the supervision of doctors and nurses. For caring for marasmic babies the foster mothers receive $15 a month, and for healthy babies $10. In this way, Dr. Josephine Baker tells me, the infant mortality was cut in half, at an expense to the public treasury of 69 cents a day; whereas the foundling asylums were formerly allowed from $1 to $2.29 cents a day for each infant, graft not eliminated, and funerals to be paid for.[2] In Stockholm, however, the cost of running the homes for mothers and babies is very much less than in New York, the amount spent for food for each mother, per diem, being only 14 cents, and, as the mothers nurse their own babies and help do the work of the home while learning the principles of infant hygiene, there is little need for doctors and nurses.

That sick children may have to be cared for in large institutions rather than in boarding homes, no one will deny. Therefore hospitals for tubercular babies and for syphilitics must be maintained in every country until these diseases are wiped out. We have perhaps not realized the necessity for the isolation of syphilitics as well as the tubercular, but recent statistics as to the number of syphilitic women in our institutions are startling. It is stated that of the pregnant women awaiting confinement at Bellevue, 25 per cent. gave positive Wassermann reactions. Dr. Jessie Fisher finds 22 per cent. positive reactions among the patients, men and women, at the Connecticut Hospital for the Insane. Dr. Edith R. Spalding finds 44 per cent. of the women syphilitic at the Massachusetts Reformatory for Women. Dr. Louise McIlroy of Glasgow finds 49 per cent. of positive Wassermanns in her out-patient clinic. But notwithstanding these figures, and the fact that every civilized country has realized that patients with tuberculosis and syphilis should be segregated, there must have been carelessness in the matter even in Germany and America to account for a part, at least, of their excessive infant mortality. In Sweden and Norway, on the other hand, where the May Flower Society has been active for many years in segregating only the tubercular children, under the care of deaconnesses and doctors, the infant mortality has been reduced 50 per cent. at one-half the cost of such institutions in our country.

Not only has New York City discovered that Scandinavia has chosen the better way, both financial and sociological, to conserve the babies, but other American cities are trying the same plans. Boston, for instance, has recently proved that visiting nurses and milk stations afford a very inexpensive means of lowering the death rate of babies, which was 134 to 1,000 births in 1910, as compared with 99.5 in 1914, a decrease of 25 per cent., with an average of 1,132 babies saved every year. In Boston, moreover, where 20,000 babies are born in a year, fully one-half need assistance, and nearly 2,000 die.

If, as Prof. Irving Fisher has shown, a baby's life is valued at $1,700, this saving to Boston in dollars and cents pays an enormous interest on the salary of its nurses and the up-keep of its milk stations, but the money, however, is as nothing in comparison with the unlimited value to the public of the educational teachings of these nurses in the homes of the badly-born and unenlightened. Boston now has third place in the list of first-class cities in the United States in respect to its infant mortality, while Philadelphia is sixth, and in the summer of 1914 Boston lost only 99.5 babies in the 1,000, while New York lost 117.

If, then, Boston's infant mortality has been reduced so much by visiting nurses, there is reason to suppose that it can be further reduced by a radical change in the institutional care of infants, as well as by new methods of caring for the poor in the maternity hospitals, and by a better control of midwives. If this is true of Boston, it is as true of all our cities. One of our best obstetricians has said that there are only a few good lying-in hospitals in the United States. Another teaches his students that every pregnant woman is in a pathological condition, and should be treated in a surgical hospital. There is evident truth in each of these statements, but without new hospitals, and even with midwives, Scandinavia has far excelled us in the saving of infants.

It is probable that the average intelligence of Scandinavian midwives is far superior to that of most of our midwives, who come mainly from the countries of eastern and southern Europe, where their training has been far inferior to the hospital training of the Scandinavians. It is said that 40 per cent. of the children among our foreign population are born under the care of midwives, whose only qualifications are that they can read and write in their own language, and that they have seen six confinement cases. In England, and France, and Germany, where for military reasons a failing birth rate and increasing infant mortality mean national disaster,[3] midwives are being carefully trained and supervised, for in these countries women have for centuries been considered the natural obstetricians. By this method alone they have lowered their mortality one-third, and if we in the United States should thus deal with our midwife problem, and by so doing lower our infant mortality one-third, we should take third rank instead of fifteenth, and if, in addition, we should give premiums to mothers who nursed their babies for two months before returning to work, as Germany has done, we might further reduce our infant mortality by one-half, and thus take our place beside Sweden in the first rank of baby-savers for, naturally, proper homing of little children would be a part of these other reforms.[4]

While paying attention to reducing our infant mortality, we should also inquire into the causes of the premature births and of the deaths of the babies who die before they have more than gasped a few times. It has been found at the Sloane Maternity Hospital that 58 per cent. of the deaths at term are from congenital weakness and atelectasis, 3 per cent. die from injuries during labor, and 4 per cent. are caused by congenital syphilis, besides another 4½ per cent. born dead probably because of syphilis. This last disease claims its toll in Scandinavia as well as in America, but with the exception of tuber-

culosis, alcoholism, and syphilis, there is nothing in Scandinavia to cause cell deterioration in both parents and offspring, or to lessen their homogeneity as a nation and their hardiness as a race. In America we have to combat ignorance, neglect, and concealed poverty. Koplik has found that 60 per cent. of our deaths in earliest infancy are due to these three causes, which do not exist to any extent in Scandinavia, where, by means of governmental supervision of the people and intelligent methods of preventing extreme poverty and neglect, there is less congenital debility, and owing to almost universal breast-feeding fewer cases of digestive disturbances and a much higher average of intelligence. This fact is brought out clearly in the death lists of Scandinavian infants in a Connecticut town where only one baby dies in a year from a population of nearly a thousand Swedes. The Scandinavian infant, therefore, starts with fewer handicaps, and even if its mother gives it away or deserts it later, its digestion has not been impaired by early artificial feeding. When the Swedish government takes care of infants in large or small homes, it continues to feed them on a diet containing at least a little breast milk, and houses them with other perfectly healthy babies, among whom there is little danger of mixed infections. Hence Sweden's 4 per cent. institutional mortality puts to shame our institutional mortality of 40 to 75 per cent.

Moreover, if our unintelligent mothers were not allowed to return to their homes from the maternity hospitals until they had lived for at least two months with their babies in convalescent homes where they could learn how to care for themselves and their babies properly, as is done in a great number of cases in Scandinavia, we should not only lower our infant mortality markedly, but also improve the health of the mothers, and prevent many subsequent gynecological operations. In Stockholm alone, for instance, a city of 350,000 inhabitants, there are between fifteen and twenty coördinated institutions for the care of mothers with their babies under government inspection. In Connecticut, on the other hand, with its population of 1,500,000, there are in all eight county homes for orphans or degenerate children over four years old, small orphanages in the three or four largest cities, two or three small homes for unmarried mothers, a Children's Aid Society, which cares for comparatively few babies in boarding homes, and an inadequate institution for feeble-minded children, none of these institutions being coördinated with the lying-in hospitals. Doubtless one State is like another in these respects, homes and asylums being under government inspectors, who make perennial visits, and report everything as in "a satisfactory condition." Recent graft disclosures in New York, however, throw some light on the high cost of maintaining such institutions. Where it is possible for a physician, not a specialist, to obtain from a New England legislature a grant of money for removing the tonsils and adenoids from every child in an institution for orphans, it would seem possible for many other abuses to be found. Humanitarian motives, doubtless, were the reasons for founding our institutions "for poor, decayed, and impotent persons," but such institutions should be sufficiently modern, and under so enlightened a board of managers that the inmates, young or old, should be fitted in them for life and not for death. In one of our most progressive States, for example, the infant mortality under one year of age was 37 per cent., until the largest cities of that State took the matter in hand. Then, by more careful housing and inspection of homes, together with the coöperation of visiting nurses and milk stations, they cut this rate down to 10 per cent. in their most crowded districts.

But even now the infant mortality in New England is not as low as the average low figure of Norway and Sweden. Perhaps to understand the reasons why this is so we might go more into detail as to the baby-saving methods employed in Scandinavia, beginning with the personal work of Professor Medin, in Stockholm, who revolutionized the teaching of pediatrics in the University Medical School. His foundation was laid upon the precept that no milk was like mother's milk, and as his Swedish mothers were strong they were able to nurse their babies provided they had good food and were not overworked. Then he believed in isolating all sick babies with their mothers, and allowing no children to visit any foundling asylum, because of the danger of infection. He does not believe that tuberculosis of the bovine type is ever the cause of human tuberculosis in babies[5], and he says that he has never seen a case of tubercular infection not of human origin. Before Professor Medin retired from his University work, at the age of sixty-five, he was instrumental in building the Sachs Hospital for Sick Babies. Here his theories for the nourishment and treatment of sick infants from all parts of Sweden are put into practice. The hospital has room for fifty-four babies, four wet-nurses, a resident physician, and the other personnel of such an institution. It is built on a bluff above the fjord, in a most beautiful location, isolated from all other buildings. A mother may live in the hospital with her baby if necessary, or she may visit it during the day to nurse it, according to its needs. The milk of the wet-nurses is squeezed into bowls and kept on ice until needed for some formula. No goat's milk, albumin milk, nor pasteurized milk is used in the formulæ, but cow's milk may be modified with buttermilk, flour, sugar, and human milk, these formulæ being represented graphically, in blocks of color, on a chart at the foot of each bed. There are four wards, each containing eight cribs; there are also eight single rooms provided with double doors and double windows, in order to assure freedom from noise and a constant temperature for premature babies. There is one head-nurse who prepares all the formulæ with the aid of servants, two ward nurses, and fourteen pupil nurses who spend three months at this hospital as part of their general training.

When we consider that in a hospital for infants too ill to remain in any other institution there can be maintained a mortality of only 4 per cent., we are not surprised that in the foundling hospitals the mortality is only 3 per cent. among 300 well infants under two years of age. This is perhaps the more remarkable to us from the fact that these hospitals are not built on a new model, the wards being dormitories where twenty-four babies sleep, or sixteen babies and eight mothers; and yet there is no "congenital debility," and there are no epidemics of measles or other contagious disease, to disturb the routine of the institution. The entire expense of running these homes is 70 cents per capita a day, including the cost of food, at 14 cents, and attendance. Much of the work of the institution is done, naturally, by the mothers who nurse their own babies; whatever extra milk they may have being bottled for other babies, provided the mother is free

from syphilis. After these babies are weaned the mother of any child may relinquish it to the institution by making a cash payment of $200. If a child is adopted into a family the institution has the supervision of it until it is seventeen years old. If it is not adopted it is sent to one of the many boarding homes throughout the country, where from twenty-five to fifty live under healthy conditions, learning, as they grow up, all kinds of housework and market-gardening. In these homes each child costs the institution 50 cents a day. If they live with foster-parents the institution, or the government, pays $30 a year for their keep. It would seem that the Scandinavians had reached the lowest possible figure for the welfare of the foundlings as well as the lowest possible mortality, the death rate in the country "homes" averaging 2.8 per cent., while the death rate in the cities is 7.46 per cent.

If one visits these homes for children one finds them plump and happy. They are satisfied with a simple diet of, for example, cereal and milk for breakfast, fish soup or meat stew with bread and butter, fruit or a simple dessert for dinner, and rice cooked with prunes for supper. They sleep in one dormitory without an open window, but with doors open into the matron's or deaconness' room. In Norway many of the children in these institutions are from homes where one or both of the parents have tuberculosis. In a home of this type in Bergen, on a hillside above the fjord, there were thirty-five boys and girls between eight months and eleven years of age, six being from one family, the mother of whom was dying of phthisis. The mortality of such children is 8 per cent, but they are sent to hospitals or sanitariums as soon as they begin to show signs of any disease.

It might be asked if these statistics of the infant mortality in Scandinavia were carefully computed, or if the deaths at birth, or the still-births had been registered. This question has been answered by Professor Johannessen[6] of Christiania who has shown that while it cannot be proved that every illegitimate birth is recorded, it is probable that very few escape the vigilance of the authorities, so that while the deaths among the illegitimate are twice as high as among the legitimate, even this figure is less than half the corresponding rate in Berlin. In Norway, as everywhere, the death rate among the well-to-do is much lower than among the poor, rising to 9 per cent. among the poor, 12 per cent. among the very poor, and 19 per cent. among the illegitimate. That there are a great many unmarried mothers in Scandinavia can not be doubted, for they are found in every country where there is a standing army of underpaid and underworked men. The condition is so ordinary that in one of the largest art-museums in Norway there is an enormous painting entitled, "A young mother kills her illegitimate baby in a cow shed." The museum paid a large price for the picture, critics hung it in a prominent place, and crowds of visitors gaze at it as a work of art, without apparent horror or sympathy.[7]

Most of the illegitimate babies are born in the maternity hospitals, many of which are modern and thoroughly practical. The patients enter the hospital in labor, are bathed in shower baths, examined, put to bed in the delivery room, and delivered by midwives or by obstetricians. After a few hours' rest they are taken into a ward, and the following day the baby is baptized in the presence of its father, if possible; it receives its father's name, and frequently a wedding follows this simple ceremony, the mother going to his home after two weeks. If, however, the father can not be induced to marry the mother of his child it is baptized with his name, and the mother takes it to one of the many convalescent homes for a few months, where she partly supports herself by working as laundress, or by sewing. The government allows only about $10 a year for the support of the woman, the rest she must earn.

In a country like that where mothers nurse their babies, milk stations are not so necessary as diet kitchens and school dinners, such as are provided in all the cities of Scandinavia; for it is recognized that if a mother is to nurse her baby she must have nourishing food, and if a child is to grow strong and robust it must have a well-proportioned diet. In the villages, on the other hand, the problems are more serious. The government, while receiving little revenue from many of its isolated communities, is obliged to provide doctors and midwives for the inhabitants, as well as schools and churches, and employment for women whereby they may earn money during the long winters. In northern Sweden there is one State-paid midwife to every 6,046 persons. Her salary is 300 kronor a year (about $84), plus two kronor for each new baby. In the more populated places in the south of Sweden there is one midwife to every 3,274 persons, at twice the salary. In Norway the doctors and midwives in the country undergo great hardships during the long winters, for the distances between farms or settlements are great, and travel by water or around the mountains is slow and cold. Were it not for the hardiness of the inhabitants of the seashore and dark valleys the mortality would be very great, for it is difficult to obtain medical help in emergencies. But where human beings are aggregated together for warmth, like sheep, in closely shut cottages, tuberculosis thrives. Hence the need for the philanthropic May Flower Society, and its intelligent care of the pretubercular cases, as well as of those who have the disease.

In speaking of Scandinavia one is apt to overlook the little country of Denmark, once the most powerful nation of the group. Until recently this country has treated its problems after the manner of Germany, and its infant mortality from cholera infantum has been high. Professor Hirschsprung of the University in Copenhagen, was however famous as a teacher and writer on pediatrics. He reduced the infant mortality 50 per cent. during his working years, but he could not obtain the low figures of Sweden because his government was not awake to its responsibility in the matter, and the farmers preferred to export all of their dairy products, while the mothers were obliged to work hard on the farm and eat poor rations. Where mother's milk and cow's milk were lacking, and where cholera infantum was endemic, the difficulties in saving the babies were great. A tea made from blueberries, and a soup made by boiling bread in beer, could not remedy an original loss of digestive function in a child. Hence the wonder is that Denmark's infant mortality was as low as 15 per cent. when that of Germany was 19 per cent. Now, however, Copenhagen has a great new hospital with an up-to-date pavilion for children, as well as pavilions for all the other departments of a university hospital and medical school. Under Professor Bloch the students are obliged to take a course in pediatrics, and to work out percentage and caloric formulæ. The city has

its milk-stations, and its cottage homes for foundlings, so that one easily understands why its infant mortality has now dropped to 10 per cent.

There are several inferences to be drawn from the preceding brief accounts of the factors concerned in lowering the infant mortality in Scandinavia, one being the evident superiority of the institutions in those northern countries over many of the American institutions. When one visits the hospitals or clinics in the large cities one is impressed with the greatness of their surgeons and doctors, and with the team work of the faculties as a whole. Many of these men have international reputations, among whom we might mention Rovsing and Hirschsprung, of Denmark, Johannessen and Strumm, of Christiania, John Berg and Oskar Medin, of Stockholm, each of whom gives, or has given, his best hours to the university or hospital, and to the public what remained of strength and enthusiasm. Evidently, then, a paternal government and a high rate of taxation, by means of which the rich are compelled to care for the poor, have been succesful in improving the health of the Scandinavian people. It is, moreover, evident that neither the size of the hospital nor the number of beds in a ward, nor midwives, nor maternity hospitals, nor pasteurized milk, have been the cause of the low infant mortality; but the lessons for Americans are essentially the following. We must have intelligent, healthy mothers with breast milk for their babies. We must train our midwives to care for the poor in their homes. We need better teaching in pediatrics and obstetrics in our medical schools. And we should build more sanitary small homes for our foundling infants, or see that those who are boarded in families are cared for properly. When we shall have achieved these reforms we shall find our economic conditions improved, and with lessened expense we shall have a much lower infant mortality.

Besides these lessons for the saving of infants, Scandinavia teaches one the necessity of more rational methods of administering charity as well as laws. Where a government supervises the building of homes for workmen it prescribes the rate of interest which may be taken from the rent of such homes, and keeps the prices of dwellings within the reach of the laborers. The parks and the waterfronts of the Scandinavian cities are kept clean and attractive for the good of the people as a whole. Doctors and hospitals are provided for the poor, as well as school teachers and priests. Women of the higher classes are appointed inspectors of the poorer districts, and these inspectors are in reality friendly visitors who give advice and alms when they find it necessary. Deaconesses, many of whom are trained nurses, go about among the poor, caring for the sick and infirm as they do in this country, but their charges for nursing are within the means of all but the poorest, for there are State pensions waiting for them in their old age, and comfortable homes provided by the government. Their nursing is more of a mission than a means of livelihood. Moreover, the public schools are possibly the greatest part of this entire system, for there not only is the mind of each child developed to its particular capacity, but from its teeth to its feet the child is cared for; its physical needs are satisfied by food which it learns how to prepare, and its body trained by gymnastics. Children study harder, play better, obey more promptly, and eat much more simple food than American children. For these reasons the health of school children is more uniform than it is here, and their death rate is half that in the United States.

It must be admitted that there is a great deal of insanity in Scandinavia, and a deplorable amount of tuberculosis, but, apparently, neither the infant birth-rate nor the mortality is influenced by these diseases, for the men and women in general are healthy, and their out-of-door life keeps them strong. And yet, ten years ago the infant mortality was double what it now is, although the adults were seemingly as robust then as now. The net result, therefore, of this survey of the causes of a low infant mortality in Scandinavia points once again to the quotation with which this article was begun, and which, in two words, means "health education."

REFERENCES.

1. Dr. Rowland G. Freeman says he believes that the mortality of well-cared-for babies is scarcely more than one-half of one per cent. Not one baby in one hundred and twenty consecutive cases in his private practice died during the first year. Moreover, he finds that a group of children from intelligent parents grow heavier and taller than similar groups of institutional children who are well cared for but not well born. (*Am. Jour. of Diseases of Children*, November, 1914.)

2. This fact is brought out by Prof. K. Stolte, of Berlin, who believes that the treatment of a baby must be individualized and that someone must act as its mother, playing with it and sometimes even nursing it before its time if it seems hungry. This is surely a scientific heresy, although emanating from a German. (*Jahrbuch für Kinderheilkunde*, Berlin, 1914.)

3. In 1914, in England and Wales the number of births was 23,000 less than the average of the five preceding years. In Berlin there were 3,500 fewer births in 1914 than in 1913, and 1,600 more infant deaths. In fact, in 1914 Germany's infant death rate was higher than that of any other country of Europe except Russia. These facts are given by Dr. Alice Hamilton in the *Survey*, January, 1916.

4. It has been found in Germany, that during August only forty-two breast-fed babies die, as against 260 bottle-fed babies. Miss Lathrop of the Children's Bureau recently verified these figures by an investigation at Johnstown, Pa., and found that among the poorer working people who did not nurse their babies the infant mortality was five times greater than among the well-to-do who nursed their babies.

5. Other excellent authorities estimate that 25 per cent. of all tuberculous children under five years old suffer from infection of bovine origin; and that bovine tuberculosis causes from 6 to 10 per cent. of the deaths from tuberculosis in children of this age. (McCleve, T. C., *Cal. State Medical Journal*, January, 1914.)

6. See articles by Prof. Dr. Alex. Johannessen, Christiania, 1902 and 1908: Dϕdeligheden i Norge af Bϕrn under 1 Aar. Also, De Forskjellige Dϕdsaarsagers Indflydelse paa Spaedbarnsdϕdeligheden i Norge.

7. In Norway, Johannessen states, the greatest death rate is at birth; 223 in 10,000 dying from congenital debility. Of the remaining deaths digestive diseases head the list, causing three times as many deaths among city babies as among those in the country. If convulsions and teething, as causes of death on the certificates, are counted among digestive disorders, the rate of deaths is raised to 3.4 per cent. in Christiania, as against 2.4 per cent. in the country. The number of cases of digestive diseases drops one-half after the first year, while contagious diseases double. Pneumonia is third on the list of causes of deaths, infectious diseases fourth, and tuberculosis fifth.

Carcinoma of the Colon; Its Early Recognition and Removal.—Rowlands states that in complete obstruction one of the following steps should be adopted: 1. Colostomy above the obstruction and well away from it. 2. Short-circuiting, such as ileocolostomy. 3. Resection with drainage after Paul's method. If the obstruction is incomplete the bowel must be emptied and the patient carefully dieted for a week before the operation of resection is attempted.—*Guy's Hospital Gazette.*

THE PHYSICIAN AND PSYCHOTHERAPY

By SMITH ELY JELLIFFE, M.D., Ph.D.,

NEW YORK.

Dr. X———:

Dear Sir—The fact that you are one of the translators of ——— has led me to address this letter to you.

My husband suffered a complete nervous collapse in July, 1909. He was pronounced a victim of neurasthenia by local physicians, which opinion was confirmed later by Dr. Y——— of B——— Hospital for the Insane. The patient took medicine under direction of Dr. Y——— for two years. Rest and change of scene have greatly improved but have failed to cure. He is possessed by worry, indecision, nervousness, etc. I desire to find a physician who uses psychoanalysis in the treatment of nerves. Our local physicians seem either afraid or ignorant of that method, and I have failed utterly in gaining any help in looking up the proper person to consult. My means are limited, but nevertheless I am prepared to make great sacrifices for sake of treatment.

Will you recommend someone that uses this treatment? Our need is very great, and that is my only excuse for asking this favor from a stranger.

Thanking you in advance for the courtesy of a reply, I am,

Yours truly,

Mrs. A.

"Is there no balm in Gilead? Why, then, is not the health of the daughter of my people recovered?"

The culture wrested from the centuries which have intervened since this cry went up from an ancient prophet of mankind has brought us much of advantage. Science has put into our hands countless tools by which we can further comfort and health. We should be masters of the art and practice of complete health. And still the cry is heard. "The wise men are ashamed, they are dismayed and taken. . . . They have healed the hurt of the daughter of my people slightly, saying, Peace, peace; when there is no peace."

It is not the stirring of sentiment to bring back this ancient outcry against the failure of those in high places to minister to the profoundest human needs. Our physicians occupy to-day this exalted station, and still an incessant and increasing call for help falls vainly upon our ears. It is not desire and purpose to help that are wanting. It is, nevertheless, lack of sympathy in the truest sense of the word, sympathy which is understanding. The physician has compassion in that the sufferings are too often likewise his own, but the deeper understanding which could bring relief is somehow not his. Perhaps a little research will reveal some of the causes for this darkening of our understanding, and therefore our failure just where the need is most pressing.

What is the reality of this human cry in its modern form? No prophet stands upon the mountain top to voice the burden of a suffering people. The complaint, however, is no less insistent. Its force is the noiseless current, often, of the soul weighted by its own inner conflict or of the helpless witness of such an unspoken conflict in a cherished relative or friend. To one of the many who have tried to understand this fundamental situation as the cause of the most grievous and widespread ills of modern life there come repeatedly such letters as that which stimulated this short paper.

A wife writes for advice in choosing medical assistance for her husband. He has been a nervous wreck for a number of years. He has seen twenty doctors and more. Medicine was prescribed for him for two years, the result of which the letter does not mention. It however goes on to say that "rest, change of scene have greatly improved but have failed to cure. He is possessed by the worry, indecision, etc., of nervousness." The same familiar story. The profound burden of these words falls only upon those who have borne it themselves, or upon those whose vision has been directed by psychoanalysis and clarified by the courage of self-analysis to penetrate beneath the surface of the conscious life into the immeasurable territory of the unconscious, where the deeper life of man is hidden, and where the mighty racial forces which have made civilization, and those that would hinder it for the sake of primary individual freedom, strive in titanic conflict. The stifled cry, checked by the impulses we call pride, humility, self-distrust, regard for our fellow men, reveals only in partial glimpses the existing struggle.

The letter here referred to represents the condition of many. The world about us is full of this sort of resigned, hopeless struggle, or of determined but futile efforts to rid oneself of such unsocial, unproductive forms of behavior, or again of those who have found a false refuge even more useless and vain and pitiable. The entire strength of science, of new thought, and of the thousand and one cults, lies in the fact that the regular profession is too busy with things material to interest itself in the mental or spiritual life of the multitudes.

Is it not high time that we awaken to the meaning of such phenomena? That we look about us to see if there is any way by which we can understand their intrinsic, their actual meaning, in order to find and utilize the remedy? Physicians have not been wholly idle nor indifferent. Yet ignorance and lack of understanding have led to an apparent indifference, to a condition of mental slothfulness and moral cowardice which was expressed very recently by one physician, who said, half humorously, wholly seriously: "Oh, I never have anything to do with neurotics. I send them out at once." Others have manifested the helplessness that paralyzes even sincere effort to relieve suffering, and have prescribed rest, travel, amusement, aimless occupation, all the accessories of therapy which fail because they ignorantly condemn a patient to palliative measures which only perhaps condemn the sufferer to a little further attempt to repress an irrepressible conflict, while in reality the secret struggle accompanies him on his journeys, thrusts itself upon all this occupation, stalks like an unwelcome, ghostly guest at every festive scene, making a mockery of the measures prescribed by the physician or urged by solicitous friends. Too often, also, enormous expense is incurred, and prolonged in the fruitless efforts of escape, and the very hopelessness of cure is even notoriously capitalized. The intense reality of the individual struggle recognizes all too clearly the ineffectualness of such means. They palliate the "hurt" and cover it "slightly," but such measures have too long cried "Peace, peace, when there is no peace."

There is one, and only one, way to remedy this state of affairs. That way is to set to work to understand why men and women and children are suffering from nervous and mental disturbances and the tremendous significance of these maladies in regard to their cause and as to what must be done about it.

This, it will be said, is what physicians have tried to do. But they have not succeeded in the unraveling of the psychoneurosis of which all hu-

manity has a trace. Freud, however, through careful experimental work, and with a sublime courage, discovered a method of penetrating the deeper and vaster portion of a man's life than that with which we are accustomed to reckon, a territory hardly suspected, and surely not understood. There lie all the forces of the past which have made the race and the individual, and these forces are still active, still striving for mastery the one over the other. The recognition of this is more revolutionary than appears at first thought. The comprehension of the fact demands further profound consideration of the widely diverse character of these forces and their antagonism and incompatibility. This necessitates a knowledge and understanding of biological evolution and of anthropology in order to know the instinctive forces in their intrinsic nature and the gradually advancing modes of expression through spiritualization or sublimation of the same. Only thus can we realize why they are factors to-day in the normal outflow of energy, or for the blocking of that energy which causes maladaptation to social requirements and the concealed internal struggle, which breaks forth to consciousness in the disguise of all sorts of painful or unproductive symbolic symptoms.

The courageous investigations of Freud and his followers into this darkened portion of man's nature disclosed this immeasurable stream of energy or libido, a force that cannot be abated, only diverted, dammed, and introverted through the inertia which is a psychological feature of infantile and primitive feeling, which produces and fosters the overwhelming desire to return to infantile and primitive conditions and modes of reaction which reality sternly forbids. Hence the strong repression of this antisocial attitude and those lawless individual tendencies which mark it; hence, also, the failure of repression, the yielding to the infantile pull which occasions the conflict, or the complete yielding which shuts the individual away into a thoroughly unsocial world of his own.

Is it the self-knowledge which this theory of psychoanalysis involves which makes it so difficult of acceptance? For, of course, it precludes a distinction in kind between the mental life of the sick and the well. Only a difference of degree of adjustment to reality and of freedom from infantile dominion exists. Therefore, our acceptance of the theory demands an acknowledgment of inacceptable impulses existing within each one of us in all their primitive and infantile egotistic force. It demands, also, that we search out and understand these impulses, and see whether they master us or are our servants. They court disguise, so that this involves a thoughtful psychological attitude and unwearied searching into all the history of mankind in order to discover his modes of expression and the means of disguise universally employed; to discover, also, the mistakes into which the infantile mode of thought and action have led man away from the pathway of achievement and advance, as well as his victory over the inertia and self-seeking which has brought the race onward.

All this is necessary equipment with which to approach the problem of individual mental and nervous disease. For the individual repeats the history of the race. A knowledge of one acquaints us with the real nature of the other, and gives the only means of intelligently and effectively handling the complex entanglements into which the fundamental struggle of impulses, rendered keener and more insistent by the increasing demands for repression which follow advancing culture, has plunged vast numbers of our population.

It may be said that other means than psychoanalysis are just as good. Let us grant this, and use those means, if they exist. If there are other methods of thought and of therapy which have the courage and the indefatigable industry to penetrate the unconscious realm, the harboring place of all the mysteries and terrors of mankind, and to recognize this unconsciousness as the heritage of every one, the physician, as well as the patient before him, by all means let us use them.

These possibilities determine the opportunity and the responsibility of the physician toward psychoanalysis. It is the most effective tool yet fashioned with which to discover the psychic needs of mankind and to meet them. Therefore, we cannot pass it by in indifference or fear. It is in its use that it may be rightly valued, as well as perfected where it is incomplete. It grants much to those who employ it carefully and conscientiously in knowledge, understanding, genuine sympathy, and one's own increasing self-control and effectiveness. Its demands are even greater. It lays upon the physician the responsibility of reaching the distraught mind in its suffering and incapacity for life, of restoring such a mind by patient, unremitting effort, a slow process when dealing with the delicate intricacies of the human psyche, to a new confidence in itself in independence and freedom from infantile forces. It makes him the conductor of the new-born soul into a freedom which is racially productive and creative. He must bear in mind that he works hand in hand with the patient, who learns the first principles of independence by sharing in the labor of the analysis. Together they have discovered the undiminished energy, the immortal libido, and learned to free it from its bonds. Their last and greatest task is then to direct this libido into progressive, constructive paths, to set it flowing free, satisfied, and in harmony with any demands reality may make upon it, because pouring outward. Introversion brought no satisfaction. The libido finds at last what it sought there in vain. It expresses now its true nature, in which alone it can really live, for to it belongs "the glory to go on and to be."

Psychoanalysis, however far it may in itself need completion and perfection, opens up limitless possibilities and opportunities, because it deals with human life as it sweeps back into the past, as it extends in breadth and intensity into the future, and because it considers it not merely as a whole, but in relation to individual complexities and individual relationships and adjustments to the whole, and to individual share in the racial task. Beware, then, lest we pass by on the other side. Let not our "wise men be ashamed, dismayed and taken," and cry "Peace, peace, when there is no peace."

64 West Fifty-sixth Street.

Obstetrical Anesthesia and Analgesia.—Frisbie concludes that in scopolamine, morphine, or narcotics we have a valuable method of relieving a very painful stage of labor if used with necessary care; that the dosage advocated by most authorities is higher than is needed to secure a sufficient degree of analgesia (most mothers do not demand complete relief from pain); that its safety and value may be greatly increased by combinations with other anesthetics such as nitrous oxide during the secondary stage or chloroform and ether in the perineal stage.—*New Mexico Medical Journal.*

MEDICINE AS PRACTISED BY THE CHINESE

By WILLIAM W. CADBURY, M.D.,

CANTON, CHINA.

PHYSICIAN TO THE CANTON CHRISTIAN COLLEGE.

SINCE the opening of the Canton Hospital in 1838, the advance of Western medicine in China has been gradual but continuous. Of recent years the medical profession of the United States has shown considerable interest in the hospitals and medical schools established by missionaries, and this interest has been greatly intensified by the recent announcements of the China Medical Board of the Rockefeller Foundation that it is their intention to assist and carry on the institutions already established at Peking and Shanghai. It is the purpose of the Board to make the schools equal to or even better than any now existing in the United States.

In view of this greater interest of the medical profession of our country, there is doubtless more or less speculation as to what is the status of Chinese Medicine as it has existed and still exists among the people of this vast Empire. The notes here submitted are partly the result of personal observation in the city of Canton, and partly of conversations with a Chinese doctor of the old style. I have also referred largely to the articles noted below under references.

Medicine in China may be considered under two divisions—the purely superstitious, which depends on charms and magic and is largely fostered by the Taoist priests, and the art of medicine as practised by the Chinese doctor. These two phases of treatment of the sick are closely interwoven with one another so that it is sometimes impossible to draw the line between them.

Let us first consider the superstitious practices and beliefs. In the city of Canton may be found temples dedicated to the "Spirit of Medicine," or healing. The ignorant people, especially women, believe that the deity presiding in these temples can restore health upon the payment of small sums of money to the priest and the performance of certain rites.

Chinese medicine like philosophy rests on a dualistic basis. At the bottom of all the laws of the universe are two principles, the "yang" and the "yin." They are generally represented by a circle divided into two parts, each of which is a comma shaped object resembling a serpent. One is white and the other black, or one is green and the other red. The circle represents the great absolute and the two divisions within it the "yang" and the "yin." Again the "yang" or male element or force is represented by straight lines, and the "yin" or female element by broken lines. Thus the pantagram was devised by a Chinese Emperor about the year 2900 B. C. This is made up of combinations of straight and broken lines surrounding the circle and its two divisions, making a perfect emblem of the balancing of the forces of the universe. Over many a doorway in China this sign is displayed to warn off evil spirits. The principle of duality typified by the "yang" and "yin" is more comprehensive than "male" and "female." They stand for positive and negative, the sun and the moon, light and dark, acid and base, heaven and earth, and they correspond to Ohrmuzd and Ahriman of the Zoroastrians, Osiris and Isis of the Egyptians, the even and the odd of Pythagoras.

The universe with its dual forces is a Macrocosm. Man is the Microcosm. Thus we read that as heaven has its orders of stars, and earth its currents of water, so man has his pulse. As earth has its water courses, called lakes, springs, etc., so man has his courses in the pulse—the three "yang" and the three "yin."

The priests explain these forces of the universe by personifications in the form of evil spirits or devils, and the people are kept in constant fear of these demons of the air which they believe are constantly bent on bringing disease or death. Hence the many superstitious practices resorted to for deceiving or warding off the evil spirits. The priests recite incantations, paper money is burned, and the pantagram is hung over the doorway. The demons are especially fond of marring beautiful children, hence the parents invent disgusting names for their offspring in the hope of misleading these tormentors. Boys are especially liable to injury at the devils' hands. Hence a guest never inquires into the sex of a new-born child, and a boy is often dressed as a girl and called by a female name.

The Chinese physician is quite a different individual from the Taoist priest, although magic and astrology are inextricably bound in with his theories of the human organism.

The first authority on medicine in China was the Emperor Chen Long, who lived about 2737 B. C., and made a classification of some hundred medicinal plants. A later emperor wrote up medical science so far as it had progressed in 2637 B. C. In the earlier ages there was some progress in anatomy, but for the last one thousand years at least, there has been practically no advance. The profound respect for the dead has interfered with dissecting and the performing of autopsies. Again there is no cooperation between doctors and no medical organization. The so-called Imperial Academy of Medicine at Peking has no jurisdiction over physicians in other parts of the country. It is composed of the physicians to the Emperor. They give instruction to the younger members in the medical classics. Generally speaking the practice of medicine is unlicensed. Most doctors receive their library from a father or relative who also imparts the secret remedies on which his reputation was established. During his apprenticeship the young doctor diligently studies the classical books and practices palpation of the pulse. The doctor is called upon only for more serious maladies. For the simpler complaints home remedies and the formulas of old women are used. In times of war the Chinese soldiers attend to their own wounds. Advertisement is quite ethical and the office of a doctor may be recognized by the tablets displayed about the entrance, on which the skill of the physician is testified to in high sounding phrases. These testimonials are usually signed and presented to the doctor by grateful patients. The name of the doctor is of great importance, thus one hears of Dr. "Root-of-Strength," Dr. "Rhubarb" and Dr. "Salts of Hartshorne."

As one would suspect from the absence of dissection and the experimental methods, the Chinese conception of physiology and anatomy is fanciful to the extreme. The body is said to be divided into three parts: (1) the upper or head; (2) the middle or chest; and (3) the lower part or abdomen, and lower extremities. Life depends on the equilibrium of the "yang" and the "yin." It is but one manifestation of the universal life. The

body is the microcosm, the universe the macrocosm. The "yang" is the warm principle, actively flowing. The "yin" is the moist principle passively flowing. As the whole order of the universe results from the perfect equilibrium of these two forces, so the health of man depends upon their equilibrium in the body. If the "yang" or active principle predominates there is excitation; if the "yin" or passive principle predominates, there is depression of the organism. The action of these two forces manifests itself through eleven organs: the heart, liver, lungs, spleen, left kidney, large and small intestines, stomach, gall-bladder, urinary bladder, and right kidney. The lungs are divided into four large and two small lobes. The larynx passes directly into the heart, which is the organ of thought, together with the spleen. The liver has seven distinct divisions. The gall-bladder is the seat of courage. The urine passes directly from the small intestines into the urinary bladder through the ileo-cecal valve. The brain and spinal marrow produce the semen which passes directly into the testicles. There are said to be three hundred and sixty-five bones in the body.

Functionally the viscera are divided into two groups known as the six viscera in which the "yang" resides, and the five viscera in which the "yin" resides. The first group is composed of the gall-bladder, stomach, small intestine, large intestine, bladder, and left kidney, with its three heat centers the three lumbar sympathetic ganglia. The five viscera are the heart, liver, lungs, spleen, and right kidney. The diaphragm is placed beneath the heart and lungs, and covers over the intestines, spine, and stomach. It is an impervious membrane and covers over the foul gases, not allowing them to rise into the heart and lungs. The stomach, spleen and small intestines are the digestive organs. They prepare the blood which is received by the heart and set in motion by the lungs. The liver and gall bladder filter out the various humours. The lungs expel the foul gases. The kidneys filter the blood, while coarser material is evacuated by the large intestines. The "yang" which is of subtle nature has a constant tendency to rise. The "yin" which occupies the brain and vertebral column as well as the five viscera tends to descend.

Each of the organs has a canal whereby it communicates with other organs. Thus the liver, kidney, and spleen are connected with the heart by special vessels and the vas deferens arises from the kidney. Some of these communicating channels end in the hands and some in the feet. One of the vessels in the little finger is used to determine the nature of infantile diseases. Six of these vessels carry the "yang" and six carry the "yin." These two forces are disseminated through the whole organism by means of the gases and the blood. The former act upon the latter as the wind upon the sea. The interaction of these two as they circulate in the vessels produces the pulse. The blood makes a complete circulation of the body about fifty times in twenty-four hours. In these fifty revolutions the blood passes twenty-five times through the male channels or those of the active principle and twenty-five times through the female channels or those of the negative principle. The blood is said to return to its starting place once in every half hour, instead of once in twenty-five seconds, according to modern physiologists, having traversed a course of some fifty-four meters.

Each organ is related to an element: fire rules the heart, metal the lungs, etc. There is likewise a close relationship to the planets, to season, color, and taste. This interrelationship is well illustrated by the following table:—

Organ	Planet	Element	Color	Taste
Stomach	Saturn	Earth	Yellow	Sweet
Liver	Jupiter	Wood	Green	Sour
Heart	Mars	Fire	Red	Bitter
Lungs	Venus	Metal	White	Sharp
Kidney	Mercury	Water	Black	Salt

Auscultation and percussion are wholly unknown as diagnostic aids to the Chinese physician. Entire reliance is placed on palpation of the pulse and the general facies of the patient in making the diagnosis. The taking of the pulse is almost like a solemn rite.

The pulse may be palpated at eleven different points, as follows:—Radial, cubital, temporal, posterior auricular, pedal, posterior tibial, external plantar, precordial, and in three places over the aorta. Usually, however, the physician is satisfied with the palpation of the pulse of the right and left wrist. With the right hand he feels the left pulse and with the left hand the right pulse. He applies three fingers,—the ring, middle, and index finger over the pulse and the thumb underneath the wrist. Then he palpates the pulse with each finger successively. Under the ring finger the pulses of the right hand reveals the condition of the lung, middle of chest, and large intestines, while in the left hand the ring finger determines the state of the heart and the small intestines. The pulse under the middle finger corresponds on the right to the condition of the stomach and spleen, on the left to the state of the liver and the gall-bladder. The index-finger placed over the pulse of the right radial shows the condition of the bladder and the lower portion of the body, over the left radial it reveals the state of the kidneys and ureters. For each of these six pulses the physician must practise weak, moderate, and strong pressure, to determine whether the pulse be superficial, moderate, or deep. This must be done during nine complete inspirations. If the pulse be rapid the "yang" principle is predominant, if slow, the "yin" is predominant. There are twenty-four main varieties of pulse. The Chinese physician must be trained to palpate the pulse so skilfully that by this single means the nature of diseases and even the months of gestation in a pregnant woman may be determined. Ten or more minutes must be spent in the palpation of the pulses.

Sometimes a Chinese physician will consider other factors. For example, it is said that by examination of the tongue thirty-six symptoms may be diagnosed according as the tongue is white, yellow, blue, red, or black, and depending on the extent of the coating. From the general appearance of the face and nose the state of the lungs may be discovered. Examination of the eyes, orbits, and eyebrows shows the condition of the liver. The cheeks and tongue vary with the state of the heart, the end of the nose with the stomach. The ears suggest the conditions of the kidneys; the mouth and lips the state of the spleen and stomach. The color and figure of the patient also count in a diagnosis.

Diseases are spoken of as internal and external. External cases are those apparent on the surface, such as all skin affectations, tumors growing on the surface and of late all surgery has been classified as the practice of external diseases. Internal diseases include all fevers and diseases of the heart,

lungs, and abdominal organs. More specifically diseases are classified under nine heads as follows: (1) Affections of the great blood-vessels, including smallpox; (2) diseases of the lesser blood-vessels; (3) fevers; (4) female complaints; (5) cutaneous diseases; (6) conditions requiring acupuncture; (7) diseases of the throat, mouth, and teeth; (8) disease of the bones; (9) affections of the eye.

Diseases are said to be produced by internal and external agents. Among the external diseases are (1) wind, which causes headache or apoplexy, dizziness, chapping of face, diseases of the eye, ear nose, tongue, teeth, etc.; (2) Cold may cause cough, cholera, heart pains, rheumatism, and abdominal pains; (3) heat causes chills and diarrhea; from dampness comes constipation, distention of abdomen, watery diarrhea, gonorrhea, nausea, pain in kidneys, jaundice, anasarca, pain in small intestines, and pain in the feet: (5) from dryness come thirst and constipation; (6) Fire causes pain in the sides, diabetes, etc. The diseases of internal origin are classified as disorders of the gases, blood, sputum, and depressed spirits.

The treatment of disease by the Chinese doctor consists chiefly in the administration of drugs. Surgery has been an unknown art. Recently two charitable institutions have been established in Canton for the treatment of the sick according to native methods of practice. At one of these so-called hospitals I was informed that bullets were removed by placing a kind of plaster at the wound of entrance. The ingredients of the plaster have a remarkable magnetic power over the imbedded bullet and gradually draw it out through the same opening by which it entered. My informant had never seen this line of treatment actually carried out, however.

Perhaps in no line does the native practitioner show his ignorance more than in the treatment of fractures. No attempt is made to reduce the parts. A special clay is placed in a wooden bowl. The heads of several chickens are cut off, while incantations are repeated and the blood is allowed to flow on the clay in the bowl. Blood and clay are now mixed together and applied to the fractured extremity. Bandages are used to bind on thin strips of bamboo. When the last turn of the bandage is being wound on, the blood of another chicken is poured on.

The only real operation performed by the Chinese is the castration of eunuch, and castration as a penalty for adultery. With one sweep of a sharp knife the genital organs are completely removed on a level with the skin of the pubis. A metal plug is inserted in the urethral opening and a cloth rung out of cold water is applied to the bleeding surface and firmly bound on. The patient is allowed to drink no water for three days when the dressing is removed, the plug withdrawn and the patient allowed to urinate.

Coming now to the real field of the Chinese doctor we find that the number and variety of remedies recommended in the Chinese Materia Medica can only be compared to our own National Pharmacopeia. The great Materia Medica compiled in the 16th century is composed of 52 books and contains 1892 remedies. Kipling's verse applies to the Chinese as to the British people for whom he wrote it:—

"Alexanders and Marigold,
Eyebright, Orris, and Elecampane,
Basil, Rocket, Valerian, Rue,
(Almost singing themselves they run)
Vervain, Dittany, Call-me-to-you,
Cowslip, Melilot, Rose of the Sun,
Anything green that grew out of the mould,
Was an excellent herb to our fathers of old."

The drugs and other medicaments are weighed out according to a decimal system as follows:—

1 tael or leung	equals	40.00	gm.
1 tsin	"	4.00	gm.
1 fan	"	.4	gm.
1 lei	"	.04	gm.
1 ho	"	.004	gm.

Often a prescription is given because of the resemblance of the drug to the organ affected. Thus for renal diseases, haricot or kidney beans are given. Minerals are administered as salts. Plants are used in the form of roots, stems, leaves, flowers, and dried fruits. The bones of a tiger are frequently ground up and given to a debilitated person. The grasshopper is dried and used as a medicine and the shells of the cicada are collected from the bark of trees and mixed with other ingredients. Tinctures and extracts are prepared from rice wine. Pills are often made with a thick shell of parafine which is broken off and the contents chewed up. Various forms of plasters and blisters may be applied to the skin. The actual cautery is often used as a revulsive.

Among the pills the best are the "Wai Shaang Uen" or life preserving pills costing about a dollar apiece. They are composed of Manchurian ginseng, deer's horns, and other drugs. Among other common remedies may be named dried, powdered rattlesnake skins, the bile of the ox and dog for jaundice, dried shrimps, etc. Quicksilver is often poured into gun-shot wounds in order to dissolve the bullet. In some drug shops two signs are hung at the entrance; on one are written the names of venereal diseases, on the other such diseases as hemorrhoids, wounds, ulcers, etc. The patient explains in which class his disease belongs and is promptly given the appropriate remedy. Among the most used drugs are some that are found in the western pharmacopias, viz., ginseng, rhubarb, sulphur, pomegranate root, aconite, opium, arsenic, and mercury.

Diseases of the liver and eyes, which are sympathetic organs, are cured by giving pork's liver. In Kwangtung Province human blood is considered an excellent remedy and at executions people may be seen collecting the blood in little vials. It is then cooked and eaten. A genuine prescription written by a physician to be used as a laxative was composed of Rumex hydrolepathium, Quercus glauca, Sodium sulphate, and Magnolia hypoleuca. The parts from these plants are boiled with the sodium sulphate and the "tea" is drunk by the patient.

A remedy which I have not infrequently seen applied to a patient *in extremis* is as follows:— A rooster is killed and the body is cut in half, longitudinally, and the bleeding half is quickly applied to the skin of the patient's abdomen. If there is any possibility of cure this is supposed to be infallable.

The use of the acupuncture needle seems to be seldom resorted to in the neighborhood of Canton. The theory on which it is based is that if one punctures the blood-vessels connecting different organs the disease will be aborted. Three hundred and eighty-eight points suitable for acupuncture are described. There is a mannikin at Peking pierced with holes at all the points suitable for

acupuncture. Paper is pasted over it and students learn to find the proper holes through the paper. The needles vary from 1½ to 28 cm. in length and are made of gold, silver, or steel. During the operation the patient coughs and the errant humours are directed back into their normal courses.

Such in brief is medicine as it is practised by the Chinese doctor of to-day. One is reminded of the old humoural theory of Europe in the Middle Ages. But modern education in China has brought a new light to the people and in all the large cities and many of the small ones, Western medicine is slowly but surely winning its way.

THE TREATMENT OF PARALYSIS AGITANS AND ARTHRITIS DEFORMANS BY THE CONTINUOUS BATH.

By SAUL DANZER, M.D.,

BROOKLYN, NEW YORK.

ASSISTANT ATTENDING PHYSICIAN TO THE SEA VIEW HOSPITAL; CLINICAL ASSISTANT IN NEUROLOGY AT THE VANDERBILT CLINIC (COLUMBIA UNIVERSITY); ASSISTANT IN INTERNAL MEDICINE AT THE GERMAN HOSPITAL DISPENSARY.

The treatment of the chronic diseases, arthritis deformans and paralysis agitans, extends over a long period of time and is very unsatisfactory if one wishes to treat the complaints of these patients. Since arthritis deformans occurs not infrequently in young and middle aged people, the need of improving them and relieving their symptoms, if it is not possible to cure them, becomes very apparent. It is with this purpose in view that we began to work up this problem under the direction of Prof. Simon Baruch, who advised the use of the continuous bath (which is really a hammock bath in a tub of continuously running water) for these cases.

We began with a temperature of 95 deg. Fahr., which, because of its proximity to the temperature of the body surface, might exert a sedative effect.

The next question that arose was the duration of these baths. In order to get positive information on this matter, we had to subject patients to these baths for varying lengths of time. The minimum exposure was 25 minutes and the maximum was 17 hours, so that patients treated for the longer period ate and slept in the baths. The longer baths seemed preferable from the theoretical standpoint, because if any effect was to be produced on these patients, the dosage of the baths would have to be generous.

From the practical viewpoint, however, we came to different conclusions. First, because patients tried to avoid urination and defecation in the tubs (although they knew the running water would carry off the excreta). Secondly, because of the strain resulting from the maintenance of the body in the one position, which produced fatigue and gave them generalized pains and aches. It can easily be seen that both of these were bad for our patients.

We found by experience that the ideal method was frequent treatments of shorter duration. Because of the large number of cases that had to be treated at the hospital, we fixed the duration at two hours, to be given daily. After the baths the patients would receive light general massage and alcohol rubs for their systemic tonic effect.

We then had to find out for how long a period bath treatment should extend. Accordingly we gave them every day for three to four weeks and watched for results. We thus noticed that the patients would feel very comfortable during this time. If they were given for longer time (as five or six weeks) they would feel tired and weak after the baths and would not improve much, and might even complain of pains, insomnia, etc. Thus we realized that we had reached the limit, so we decided to leave the patients out of the baths on each seventh day of the week and limit the total number to thirty, which series might again be renewed after an interval of one month. By this régime we obtained very favorable results.

Upon further experience we learned that cases of arthritis deformans and paralysis agitans could not very well be treated in the same room at the same time; for while the nervous cases complained of the high temperature of the room and wanted the windows opened, the arthritics preferred the windows closed because they felt cold. Likewise, the Parkinsonian patient said that he preferred water colder than 95 deg. and the patient with the joint affection wanted the temperature raised.

Accordingly we grouped the nervous cases together and treated them at one time with the room well ventilated and the water at 92 deg. Fahr.; the joint cases were treated together in a warmer room and the bath was given at 98 deg. Thus we obtained marked improvement in both types of cases.

Results of Treatment—General Condition.—In order to observe these cases carefully, temperature, pulse, respiration, and blood pressure (systolic and diastolic) were taken a half hour before the baths and every half hour while in the baths, also a half hour after the patient came out of the bath. In general, we found that during the first half hour in the bath there was a slight fall in blood pressure, a slight increase in pulse rate and in the frequency of respiration, which soon dropped to normal. Urine examination and blood counts were taken with no remarkable results.

A fact worth mentioning is that when the patient was left in the tub too long (past the physiological dose) the pulse, respiration, and blood pressure rose, and in cases of paralysis agitans the muscular rigidity increased. Fatigue and discomfort rather than any direct effect of the bath itself may account for these symptoms.

Arthritis Deformans: Pain.—It was remarkable to see how quickly patients felt relieved when placed in the tub; even the most advanced cases showed improvement. Out of all of these cases at the Montefiore Home and Hospital, in only one case

can we say definitely that no improvement resulted and this case was one complicated with optic atrophy and blindness in which treatment had to be suspended because of the general irritability. In many, benefit was noticed after the second or third bath.

Patients who for years had to take aspirin or some other form of salicylic acid to quiet their pains and give them rest, could now get along quite comfortably with no medication at all. This was already a gain, because we were dealing with the most advanced and desperate cases of the disease. Some patients were relieved only while in the bath, while in others the improvement was more lasting.

Joint Motion and Muscular Rigidity.—These were also favorably influenced and very early in the treatment we noticed that the patients began to move joints that were comparatively stiff before. This was due both to the relief from pain, as previously described, and also because of the muscular relaxation produced by the warm water. A remarkable case that was seen was in a man suffering from arthritis deformans for about twelve years and who had not walked for the past three years. When I first saw him he was suffering from an acute exacerbation of a chronic nephritis. He was given the routine treatment and after three baths pain was relieved and he began to move some of his joints. After ten baths he walked without the help of a cane, a feat which he had not accomplished within three years. Because of the benefit received this patient asked to have his course of baths prolonged. Accordingly he received them for two weeks more during which time he steadily improved, but because of other patients waiting to receive treatments more baths had to be denied him.

Paralysis Agitans.—In this condition, as is well known, the patients complain of parasthesias (especially burning sensations) along the back, muscular tremor, and rigidity. Parenthetically, I wish to say that our routine medication for these cases was hyoscine, which in some instances had to be given thrice daily in order to obtain relief. When the bath treatment was begun, all forms of medication were stopped and patients who for years would crave for their hyoscine could do without it very well.

The parasthesias were the first to yield. As a rule the greatest relief would be obtained while in the water with a return of some pain afterwards, while in others complete improvement resulted for the time being. Muscular rigidity was also lessened, thereby giving more motion to the joints. The tremor was also diminished while in the water.

In some cases we noticed that after improving for a few days the patients became worse again, namely, their tremors increased and their rigidity returned. Upon further investigation we found that this occurrence was parallel with states of constipation, hence we tried to pay special attention to the bowels at this time and noticed that things cleared up again. Accordingly we began to prescribe light catharties and enemas every night, with very satisfactory results.

Theory of Action of the Baths.—We must now ask ourselves how do these baths act? What is the mechanism of these baths on the disease conditions? In order to answer this we must analyze the symptoms and get at their cause.

Let us consider first arthritis deformans. The pain in this disease may be due to the following: (1) Painful skin areas corresponding to the joints affected with arthritis. Because of this, irritation of the skin would produce reflex muscular spasms, thereby approximating the joint surfaces, which of course aggravated the pain, thus producing a vicious cycle. (2) A neuritic involvement, as in peripheral neuritis, since there is evidence that arthritis deformans is the result of a metabolic or toxic process.

The painful skin surfaces are relieved because of the soothing effect of the tepid water (98°). To understand this thoroughly, I would refer to Professor Baruch's Hydrotherapeutic Law. The effect of any hydriatic procedure is in direct proportion to the difference between temperature of the water and that of the skin. When the water is of a temperature above or below that of the skin, it is stimulating. As the temperature approaches that of the body surface, the effect is a sedative one. Ordinarily the skin temperature is 92° and the skin over an inflamed joint is a little warmer than over the adjacent areas; hence temperature slightly higher than 92° (95°—98°) are most sedative in arthritis deformans.

As pain and hyperirritability of the skin are lessened, the reflex muscular rigidity and resulting joint pain are diminished. The pain due to the coexisting peripheral neuritis is relieved because of the eliminative effect of the warm bath on the skin. Also because of the soothing effect as just described.

In Parkinson's disease the pain and reflex muscular spasms and tremors are in a great measure the result of an influx of stimuli coming in through the nerve fibrils of the skin. Evidence of this fact is given by the increase of all these symptoms when a cold stream of air passes over these patients or when the atmosphere of the room is too warm. Another form of peripheral irritation tending to exaggerate all these symptoms is constipation. So marked was this that one could actually use muscular rigidity as an index to the condition of the patient's bowels. Now, if the skin forms the portal of entry for the irritated influences and since water at the temperature given soothes, we can readily see how the continuous bath acts on the diseases in question.

Conclusion.—The continuous bath does not cure paralysis agitans or arthritis deformans, nor does it change the pathological process in the least. It does, however, offer great relief to these patients and improves their symptoms subjectively and objectively. It is far superior to the salicylates for arthritis deformans or hyoscine for paralysis agitans, and certainly has none of the objectionable features belonging to the prolonged use of these drugs.

As a palliative measure the continuous bath in our opinion is to be highly recommended.

660 Willoughby Avenue.

Herpes of the Cornea in Influenza.—C. W. Walker reports this case: Physician, aged thirty-four, after having treated many patients with influenza, fell a victim to the disease and developed a herpes on the right side of the face. About two weeks later a foreign body lodged in his right eye, and despite its extraction the traumatic conjunctivitis became much worse, and a few days afterward the cornea was seen to be hazy. From the very first the eye had been refractory to treatment and the effected cornea soon showed ulceration; the ulcers, however, now responded quickly to the proper treatment, leaving excentric opacities with vision intact. —*The Ophthalmic Record.*

PROCTITIS.

By CHARLES J. DRUECK, M.D.,

CHICAGO.

Proctitis or inflammation of the rectum is quite commonly met with in general practice, and requires careful diagnosis and prompt treatment. Several different varieties are distinguished, although the symptoms in general are much the same in all and the case frequently terminates in fistula.

Proctitis is divided into acute and chronic varieties, each of which has several forms, according to etiology or development. Thus the acute consists of the catarrhal, dysenteric, diphtheritic, and gonorrheal; the chronic, of the catarrhal, syphilitic, tuberculous, papillomatous, and stenosing.

The catarrhal acute form of proctitis is due to intestinal disturbances and occurs chiefly in children, although occasionally it is found in adults. Usually the mucous membrane alone is involved, being congested, even tumified at times, and the epithelial layer may be shed off during the engorgement. In dysenteric proctitis the whole colon is frequently involved, especially in the tropical variety. The rectum, like any other mucous membrane, is liable to the invasion of diphtheria, but infection is rare. Gonorrheal proctitis is commonly found in women on account of the close proximity of the vulva and rectum, and is usually the result of uncleanliness, sodomy, or abscess of Bartholin's gland that has ruptured into the rectum.

Chronic catarrhal proctitis may result from repeated attacks of the acute form or may begin as a deeper and a chronic inflammation. Constant reinfection and irritation, together with a sluggish venous flow, tend to prolong any inflammation in the rectum. In aggravated cases, the surface is granular with multiple ulcerating points. Hypertrophy of the glands occurs, causing papillomatous growths which project into the lumen of the rectum (papillomatous proctitis). When the inflammation extends deeper than the mucous membrane and involves the areolar and muscular tissues around the rectum, a constriction results later, from the contraction, and we have a stenosing proctitis.

In adults, proctitis may result from fecal impaction in the rectal pouch, exposure to colds as sitting on a cold or wet seat, foreign bodies in the rectum, hard substances in the fecal mass, as fish bones, pins, hulls of cereals; injury from the tip of the syringe, strong purgatives, or arsenic, bichloride of mercury, irritating suppositories, the extension of inflammation or colitis, or the irritating discharges from the bowel above. Esmarch reports a case of proctitis as a symptom of gout, the rectal inflammation alternating with other symptoms. Proctitis may also result as an extension of inflammation from hemorrhoids, prolapse, or eczema about the anus. Both acute and chronic proctitis may result from inflammation of neighboring organs, as the bladder, prostate, vagina, or uterus.

The symptoms vary with the severity of the attack and the duration of the trouble. The chronic forms are less painful and tender than the acute. A sensation of weight, heat, or fullness appears in the rectum and may amount to actual pain, which in severe cases may involve the uterus, bladder, and sacral region, and even radiate down the thighs. With this tenesmus, a constant and ineffectual desire to empty the bowel occurs, and this continual straining frequently produces a prolapse of the mucous membrane, especially in children. Irritation of the trigonum vesicæ causes frequent micturition or sometimes retention. By this time the engorged membrane is bleeding, perhaps with a mere streaking of the passage or occasionally considerable discharge of clear blood. Kelsey reports a case in which this loss of blood was the first symptom that attracted the patient's attention. A case of proctitis with hemorrhage without any of the antecedent symptoms is rare. Later mucous and pus are voided. Examination at this stage reveals ulceration to some extent. It may be very superficial and limited to one or two small points or have many foci, some of which may be quite deep and involve the whole thickness of the mucous membrane or even perforate the bowel. When ulceration occurs above the peritoneal fold it results in peritonitis, and when below that line in abscess and fistula. A chronic proctitis may in this way cause a stricture.

In all forms of proctitis the anus is red and painful, the sphincter and levator ani muscles are irritable and spasmodic, and associated with the local symptoms there is always more or less constitutional disturbance. In chronic proctitis, the symptoms are less marked, diarrhea alternates with constipation, and the discharge occurs only with defecation. The inflammation may be limited to only a small part of the rectum or may be more diffuse and involve all of the organ.

The symptoms of dysenteric proctitis are similar to those of the chronic catarrhal form except that more of the bowel is involved and the systemic influence is more marked. When the diphtheritic variety is found other members of the patient's family should be cautioned about using the same closet. The gonorrheal form has its characteristic free, creamy white discharge issuing from the anus, the rectum becomes hot and swollen, and the pain is burning and intermittent. The anus chafes and the sphincter is spasmodic in its action. This form of proctitis is usually of short duration and can easily be differentiated on account of the disease in the vulva or urethra and by finding the gonococci in the pus. It may, however, if untreated, degenerate into a chronic proctitis. The discharge is freer and contains more pus than any other form of proctitis. It must be remembered, though, that gonorrheal proctitis is rare; Gosselin saw only one case in three years.

The following case in my own practice some time ago gives a vivid picture of this form of trouble:

Patient referred to me by Dr. Watts and first seen by him, suffered from gonorrheal infection of the whole genital tract. Abscesses had developed in Bartholin's glands and rupturing into the rectum had produced labiorectal fistula on either side of the vagina, from which there was considerable discharge. The examination revealed sinuses into the rectum above the external sphincter. Rectal examination showed on inspection a free discharge from the vagina and also from the rectum when the patient was requested to bear down, although the sphincter which was spasmodically contracted, would ordinarily retain the discharge. The anus was quite inflamed. Digital examination showed the rectum was tender and disclosed an abrupt stricture about two and one-half inches above the anus. This stricture was at nearly the lower level of the internal sphincter muscle and was annular in shape and diaphragm in form, that is, a thin, membranous septum. No marked induration was felt at any point, but as the finger was withdrawn it was covered with blood and pus and a few shreds of mucous membrane. The specular examination was especially instructive. The active inflammation began immediately above the external sphincter and appeared localized below the stricture. The whole mucous membrane had a honeycombed ap-

pearance and was covered with white fibrous shreds resembling the "tripper-faden" of urethritis, only much larger. They were easily removed, but left the mucous membrane inflamed and bleeding. As the rectum was dilated the stricture could be seen to stretch and tear. The trouble appeared to be localized within the lower two inches of the rectum.

Proctitis is not very serious, as a rule, unless the cause cannot be found and removed. When the cause is removed the case heals kindly unless complicated by ulceration, abscess, or fistula. Sometimes a perirectal lymphangitis or phlebitis may protract the case or cause a fatal termination. Acute proctitis will pass off in ten days or so, leaving no appreciable permanent alteration in the bowel, except in those cases in which ulceration or gangrene has occurred. Chronic proctitis is liable to continue indefinitely unless the cause can be removed. The mucous membrane is thickened and indurated and loses its sensibility more or less, so that a large bolus of feces may collect without stimulating the rectum to expulsion. Stricture of the rectum generally has some chronic proctitis associated with it; below the stricture the mucous membrane is congested and covered with pus or mucous, while above the stricture ulceration occurs.

A thorough examination of a case of proctitis is important and a digital examination should be made in every patient presenting a chronic diarrhea, because many of the causes given above as predisposing to or exciting proctitis may be promptly determined. When the patient is placed in the knee-chest position, the proctoscope is well oiled and introduced, and as the obturator is withdrawn the air rushes in and dilates the bowel; then by turning the proctoscope from side to side and gradually withdrawing it the whole surface of the rectum may be carefully and thoroughly explored.

The treatment of proctitis varies considerably with the exciting cause and, therefore, before instituting any treatment a thorough examination must be made. The parts being irritated and inflamed, the examination is very painful unless an anesthetic, general or local, is administered. In many instances where for various reasons chloroform should not be given at the time of the examination, the patient may be relieved of most, if not all, of the pain by the application of a 2 per cent. solution of cocaine. A general anesthetic has much in its favor, because when the patient is asleep the sphincter may be thoroughly dilated, thus relieving the tenesmus and greatly facilitating subsequent examination or treatment. At the same time, any local trouble or cause of the proctitis may be removed, thereby accomplishing two things at one sitting.

Acute cases require absolute rest in bed, because when the patient is up and about his duties the dependent position of the vessels, together with the thinness of their walls and the associated congestion and inflammation, produce a venous stasis which seriously impedes or prevents regenerative changes.

The diet should be plain and of such a variety as will insure soft or semisolid evacuations. It is also advisable to maintain a largely absorbable dietary that the bowels may move infrequently, thus sparing local movements of the parts. Twice each day the bowel should be douched with two quarts of cleansing solution as hot as can be borne. To begin with, a temperature of 105° F. may be used and the temperature raised each day. Plain boiled water with the addition of a handful of salt has given me the best results. I have devised a douche tip of my own to be used in these cases, because I have found it impossible to obtain a free return flow with any I have found, and unless the exit is large the fluid will pass up into the colon and carry the infection up with it, instead of washing it out. By practical experience I find that douching in this manner washes out a large amount of infectious material, such as secretions, fecal accumulations, and hordes of microorganisms; dissolves mucous and pus, flushing them out as shreds; contracts the vascular structures, thereby stimulating circulation, relieving the local congestion, and depleting the tissues.

Following the douche, about two drams of astringent antiseptics or other medicinal mixtures is injected and the patient is instructed to retain it. Silver nitrate, hydrastis, glycerole of tannin, or acetate of lead in various combinations and strengths, according to the case, are the most reliable drugs. If the pain and tenesmus are not reduced, laudanum and starch water may be injected every two or three hours until the patient is relieved; from twenty to sixty minims may be needed in this way.

Hot fomentations applied over the hypogastrium give much relief when the inflammation extends over a large area and when there is general, diffuse pain and tenderness. In mild cases limited to the lower end of the rectum, the applications of cold to the anus and perineum or the injection of cold water into the rectum relieves the congestion promptly.

When the proctitis is due to thread worms injections of lime water or salt water and the administration of santonin internally will be enough. Gonorrheal proctitis, like its counterpart in the urethra, is especially intractable. Silver nitrate solutions 1-3,000 should be used to douche the rectum, but the same conditions must be observed as are mentioned above. The strength is to be gradually increased as a tolerance is established until a 3-1,000 solution is used. Following the douche the whole mucous membrane is swabbed with balsam of copaiba or a suppository containing balsam of copaiba and iodoform, each 5 grains, may be inserted.

The chronic forms of proctitis are somewhat different. The douching should be instituted in these just the same as in the acute cases because of its alterative effect. The excessive secretion is controlled with applications of alum, zinc, or silver, or any of these combined in a suppository with iodoform, or one minim of oil of turpentine.

When ulceration, periproctitis, or any other complication exists it requires its own treatment, which for obvious reasons cannot be entered into in this paper. Syphilitic cases are associated usually with strictures which may require surgical treatment, although I have seen astonishing changes occur under general internal medication. Tuberculous proctitis is usually secondary to disease higher up and is accompanied with so much ulceration, together with the general systemic infection, that treatment is unsatisfactory. The treatment of proctitis due to cancer is surgical, of course, and cannot be considered here.

Proctitis in either the acute or chronic form is always a serious matter, deserving of the physician's most careful attention because the inflammation itself may debilitate, and especially because

complications which may invalid the patient are prone to occur. Each case is a law unto itself, and this article cannot go into the details that may perplex the attendant, but simply tries to give the reader a clear clinical picture in general and to lay down the main lines of treatment.

A CASE OF LACERATION OF THE LIVER.

By C. A. WAYLAND, M.D.,

AND

R. T. WAYLAND, M.D.,

SAN JOSE, CAL.

The liver, in consequence of its anatomical situation, size, and firm attachment, becomes subject to injury when direct violence occurs against the upper right abdominal quadrant and the lower part of the thorax. Its lack of elasticity and its consistency further predispose to the tearing of this organ at the time of injury. As compared with injuries of other abdominal viscera, we find that one observer collected 365 cases, of which 189 concerned the liver and 176 represented the combined injuries of the pancreas, kidneys, and spleen. Out of the 189 cases involving the liver, 120 were located in the right lobe. Most cases are due to direct violence caused by a blow, fall, or the end of a rib penetrating its structure. A few cases, however, are predisposed by certain diseases, *e.g.* syphilis, tuberculosis, amyloid degeneration, hypertrophic cirrhosis, tumors, and malarial fever. Males are injured more frequently than females, and painters, carpenters, and railroad employees are the usual victims.

According to another writer, out of 543 cases collected 80 per cent. died if not operated upon, while the mortality following operation was from 40 to 50 per cent. A number of factors may enter into the ultimate outcome of the case. For example, a small tear through the peritoneal coat of the liver may result only in the formation of a hematoma, while on the other hand a deep laceration severing bile ducts and large vessels will cause a severe hemorrhage which will rapidly prove fatal. The admixture of bile and blood at the time of the injury probably prevents rapid coagulation. The severity of associated injuries to other organs will, of course, alter the ultimate outcome of the case. An interesting fact noted is the rapid recovery from gun shot wounds of this organ produced by the modern bullet, while stab wounds are more apt to prove fatal.

The following represents a very striking and instructive case that came under our care

Mrs. M. V., age 34, married. In good health previous to accident. On the afternoon of February 18, at 4 P.M., patient was thrown from a wagon on which was a large barrel of oil. She struck on hard ground and the edge of the barrel fell on the upper part of her abdomen. In some way she received a severe blow to the head, which was evident from the symptoms she had of concussion. Immediately following the accident she walked to an automobile and rode about half a mile. Owing to the gradual development of unfavorable symptoms we were not summoned until 6 P.M., and by this time she was in shock and the abdomen revealed signs of some intraabdominal calamity, producing hemorrhage which called for immediate operation. She was hurriedly taken to a hospital.

Rallying slowly to a state of semi-consciousness, the patient became restless and thirsty. She vomited (vomitus containing dark blood), yawned, and had air hunger. Her mind was not clear. She complained of severe pain located in the left upper abdominal quadrant, which was continuous, sharp, and cutting in character. It did not radiate. Marked dyspnea was present.

Examination showed a fairly well developed female adult. Showed evidence of collapse. Skin was a peculiar greenish white color and very cold and clammy. Both pupils dilated. The left reacted sluggishly to stimuli. There was ptosis of the left eyelid. Mucous membranes were blanched and anemic. The tongue cold, dry, and white in color. On protruding it deviated to the left side. Lips drawn to the same side. The lungs were clear and resonant throughout. Respiration labored, rapid, jerky, and limited on the left side. Heart action rapid. Sounds weak. No murmurs heard. The abdomen was distended. Board-like rigidity of the upper left quadrant; marked tenderness in the epigastrium. No masses were felt. Slight dullness present in both flanks; more marked in the left. Liver dullness not noticeably increased. Neither kidneys nor spleen palpable. The left arm and hand were completely paralyzed, but sensation was maintained. Her pulse rapidly became weaker until it could no longer be felt.

Operation.—Preparation consisted of a dry shave of the entire abdomen and the application of the tincture of iodine. Only a small amount of ether was needed, owing to the collapsed condition of the patient. An intravenous of normal salt solution and adrenalin chloride was started. A left rectus incision was made through the abdominal wall, extending from the costal angle to the supra public region. The abdominal cavity was found full of blood, and a hurried examination revealed a laceration of the left lobe of the liver. It was about five inches in length, situate at the lower anterior margin and extending up between the right and left lobes. Associated with the laceration was a gapping of the fissure between the two portions of the liver. Blood was rapidly oozing from the tear. Gauze was packed into the rent while the blood was evacuated from the peritoneal cavity and the other abdominal viscera examined, but no other serious injury was found present. The edges of the gapping wound were approximated with No. 2 catgut mattress sutures. Due to the close proximity of the suspensory ligament, a few sutures passed through it and thus not only aided in holding up the liver but also lessened the danger of the sutures to cut the hepatic tissue. Owing to the fact that the sutures at the upper angle of the laceration would not hold, an iodoform gauze pack was put in this area. A small drain of iodoform gauze was inserted down to the line of sutures, and both drains were brought out at the upper angle of the wound. The peritoneum was sewed with catgut, and through and through silk-worm gut sutures were used in order to rapidly close the abdomen. Dressings applied.

The intravenous of salt solution and adrenalin chloride was continued throughout the operation, a total of one quart of salt solution and one drahm of adrenalin chloride being given. Her pulse gradually became palpable under this stimulation. The patient was returned to bed in a very critical condition.

Following the operation the foot of the bed was elevated; the extremities were bandaged, external heat was applied, and enteroclysis of salt solution started. Camphorated oil, strychnine sulphate, and morphine sulphate were used as indicated. Her pulse remained irregular, weak, and at times could not be palpated. Twelve hours following the operation six ounces of blood taken from her brother was given intravenously. (The indirect method with sodium citrate as an anticoagulant was used.) No ill effects were noted by its use, while on the other hand she gradually regained strength. Immediately her pulse became regular and of fair volume. In twenty-four hours bile-stained drainage appeared upon the dressings and this necessitated frequent changing. This bile-stained drainage continued for about three weeks, and then gradually disappeared as the wound healed. The gauze drains were slowly pulled out until the seventh day, when they were removed entirely. On the second day after the operation she manifested evidence of a low grade peritonitis by vomiting, slight rise in temperature, and tympanites. This subsided two days later. Jaundice did not appear throughout convalescence. On the twenty-third day following the operation the patient had a convulsion, which started on the left side of the body and then became general. This was followed by a period of unconsciousness which lasted for about twenty minutes, and then she became apparently the same as before the convulsion, except that she had a complete motor palsy of the left side. This remained for two days and then gradually began to improve, until at the present time she has complete power of her left leg and

nearly the entire use of the left arm and hand. Convalescence was slow but uninterrupted, except for the one convulsion mentioned. The wound healed by first intention except at the point where the drains came out, and here granulations gradually filled in the opening. Six weeks following the accident the patient was able to leave the hospital in very good condition. At the present writing she has resumed her usual household duties.

The following points suggest themselves upon a study of this case

1. The necessity of seeing a case early and recognizing an internal hemorrhage.
2. Early laparatomy if hemorrhage is present, even though the patient is in shock.
3. Make a free median abdominal incision, using plenty of room to work.
4. Control bleeding by sutures, packing, or cauterizing.
5. Drain the site of the laceration in the liver.
6. Drain the peritoneal cavity.
7. Treat the hemorrhagic shock by replacing the lost fluid into the circulation and stimulating.

UNIVERSAL IMMUNIZATION.

By HERMAN B. BARUCH, M.D.,

NEW YORK.

For several years I have given much thought to the subject of immunization. On June 10, 1910, I proposed to Dr. Simon Flexner, of the Rockefeller Institute, to make some experiments at my own expense on injections of a serum from the blood of an equine case having a temperature of 106° Fahr., into another case with the intention of producing a premature crisis. Dr. Flexner kindly replied, October 20, 1910: "I do not doubt that there is a certain amount of toxin present in the blood of patients suffering from pneumonia. . . . It is impossible, however, for me to take up any special work in this connection since we are engaged in other problems."

On the same subject, I wrote to Dr. Henry Smith Williams on December 30, 1914, the following: "Lobar pneumonia stands as a monumental rebuke to the medical profession. Nature so plainly points the way to its cure, and yet we poor blunderers stand impotently by and it claims thousands of victims annually."

Accordingly, I engaged with the consent of the Health Department, the services of Dr. A. Silkman, Veterinarian of the Department, to elaborate such a serum from a horse suffering from acute lobar pneumonia. This work has progressed most satisfactorily to date and will be made the subject of a later communication.

Under date of August 10, 1916, I wrote Health Commissioner Dr. Haven Emerson, to furnish me with fluid drawn from the spinal cavity of a poliomyelitis patient for similar experiments at my own expense on the same horse. This I have not yet been able to undertake.

It has long been known that an attack of certain infectious febrile diseases protects the individual against a subsequent attack. More recently the theory of persistent antibodies has been accepted as the cause of such immunity. The nature of such antibodies is not at all well established, but probably they exist in the blood as hormone secretins, which have been determined to be in the nature of enzymes. As, for instance, in a patient having once been attacked by scarlet fever; if the disease is successfully combated by the system, it is because the system has reacted to the toxins of the disease and produced an antitoxin or antibody which has been generated under the influence of the hormone secretins which occur in the blood at the time of the attack and are probably produced by the red blood cells and in turn react on the blood cells themselves and cause an increase in the secretion of the antibodies or antitoxins, and when these become great enough in number or strength, the patient is enabled to overcome the toxin or poison produced by the specific organism causing the infection, and the patient recovers.

In the case of scarlatina, this immunity is permanent or practically so, and there is theoretically always circulating in the blood of a patient recovering from scarlatina, an unknown quantity of hormone secretins which are probably in the nature of a ferment. Whenever the toxins of scarlet fever or the streptococcus gain access to the system of such a patient, this toxin immediately reacts on the hormone secretins which, acting as ferments, cause an immediate increase in the antibodies which protect against scarlet fever and cause the toxins of scarlatina to be overcome and the patient is not attacked by the disease a second time.

Believing that the theory will hold good for all diseases one attack of which protects against subsequent attacks, under date of December 16, 1915, I wrote in instructions to Dr. Silkman, who was then engaged in elaboration of the pneumonia serum under my direction, as follows: "As soon as the above work on the pneumonia serum is completed, it is proposed immediately to conduct experiments with a view to obtain a vaccine or immunization against scarlet fever, measles and other diseases in which one attack prevents against future attacks. The patient having once suffered from scarlet fever, is seldom, if ever, subject to a second attack. Therefore, a permanent antitoxin is circulating in the blood of such patient and produces immunity. It is my theory that even small doses of the serum of such a patient injected into an infant or child, would produce permanent immunity. If not, monkeys of the larger type could be exposed to scarlatina or measles, or injected with the proper streptococci, or other infectious material, and a vaccine or serum worked out in this way."

So far, I have not been able to complete the latter work, but working along these lines we have obtained a serum which has been successful in a moderate number of cases in equine pneumonia. In this case, the hormone secretins are fugitive, being rapidly eliminated from the patient's system, and for this reason an attack of pneumonia does not confer immunity. This idea occurs to me as being especially interesting at this time with the unfortunate prevalence of anterior poliomyelitis in New York City and adjacent territory.

As a matter of practical moment, I believe that, if the blood of an adult be drawn under proper aseptic precautions and the serum isolated, an injection of from one to six ounces of such serum according to the age of the patient will produce an immunity in a child if the subject from whom the blood is drawn has suffered from this disease. I believe it will be possible largely to prevent the occurrence of scarlet fever, measles, typhoid fever, smallpox, typhus fever, and all diseases an attack of which produces an immunity of greater or lesser extent for the future.

The above theory may serve to explain in a way

the results which Dr. Abraham Zingher of the Willard Parker Hospital has had in the use of serum obtained from normal adults in combating poliomyelitis in its early stages.

There is reason to believe that, if children are injected with the serum drawn and prepared from the blood of their parents or other individuals at an early age if the donors have suffered from scarlet fever, measles, or any of the immunizing diseases, such offspring will be rendered immune to these diseases and that eventually it will be possible to breed a race of humans who will be progressively immune to all of the acute infectious diseases. The longevity of the race will then be vastly increased because of the large number of permanent disabilities that are produced by the so-called "diseases of childhood," and the above thought contains a suggestion which, carried out, will produce results of great permanent service to future generations as well as to the present.

It may be that experiments will prove that the hormone secretins are found in the red blood cells or in the coagulum rather than in the serum, but a carefully conducted series of animal experimentations would readily prove whether the serum alone or a combination of a saline extract of the coagulum would be necessary to produce the desired result.

The terrible results of the present epidemic and the large number of cripples which it will undoubtedly leave in its wake, in addition to the death toll of 20 per cent, should make it well worth while to attack this problem when the present excitement has subsided, so that the future may not see the anguish and suffering which the present affliction has brought to all of us who are parents and have the responsibility of such cases upon us.

A FATAL CASE OF POLIOMYELITIS IN AN ADULT.

By J. GARDNER SMITH, M.D.,

NEW YORK.

THE following account of a fatal case of poliomyelitis in an adult may be of interest. An apparently healthy young man of twenty, whose home was in the best environment in upper Manhattan, worked in a large, airy architect's office in Brooklyn. Saturday noon, July 29, he ate lunch downtown, carried his dress suit case and a small tent to a New Jersey town; pitched some hay in the afternoon, ate a hearty dinner, pitched his tent and slept on the ground that night. He was awakened by the great explosion, walked a mile and back to the tent, where he slept the balance of the night. On Sunday he complained of headache and sore muscles, but returned to New York that night, ate heartily, took a bath, retired, and slept fairly well. Monday morning he vomited and complained of severe headache. He was seen in the evening by Dr. Clyde K. Miller. The patient at that time complained of headache and stiffness of neck and muscles, but had no fever; he was given a laxative. Tuesday morning the patient could not wind his watch and paralysis of the arms progressed. Wednesday morning he could not raise his arms from the bed; could rotate arms and forearms slightly; chest muscles paralyzed. Reflexes of lower extremities exaggerated; Koenig and Babinski tests positive. After consultation with the Health Department and Research Laboratory I made a personal call upon Dr. S. J. Meltzer. We followed Dr. Meltzer's suggestions. At 5 P. M., 10 c.c. of clear spinal fluid withdrawn and 2 c.c. of adrenalin injected; 10 P. M., 20 c.c. of fluid withdrawn and 3 c.c. of adrenalin injected. Thursday, 1 A. M., 5 c.c. withdrawn and 2 c.c. of adrenalin injected; 5 A. M., 10 c.c. withdrawn and 3 c.c. adrenalin injected; 10 A. M., 4 c.c. withdrawn and 2 c.c. adrenalin injected. The last injection was given at 2 P. M., 4 c.c. withdrawn and 2 c.c. adrenalin injected.

The patient also received urotropin 5 grains every four hours and oxygen under pressure was administered with Dr. Meltzer's apparatus (obtained from Tiemann & Co.).

Thursday, 10 A. M., there was a distinct improvement; the patient could flex his arms across the body and could use his thoracic muscles; but he had difficulty with the muscles of the neck, throat, and tongue, and some ocular palsy was present. About 1 P. M. paralysis above the waist increased. He became irrational, and at intervals was deeply cyanotic. He died at 7.40 P. M.

This very bad case seemed to be fatal from the start; it presented a mixture of the encephalitic and bulbospinal types. The paralysis spread rapidly. Death occurred probably from paralysis of the respiratory and vasomotor centers. The adrenalin treatment was begun very late and very little hope could be entertained regarding its effect. Nevertheless, after the fourth injection an unmistakable improvement in the spinal paralysis took place. Regarding the question whether adrenalin could accomplish a cure, Meltzer says (MEDICAL RECORD, July 22, p. 160) that on account of the comparatively low mortality of infantile paralysis it could not be answered for some time to come. "However," he says, "there is one form of evidence which is of actual value and that is when an improvement is observed which has to be ascribed to the treatment." It seems to me that the present case offers such evidence.

The questions unsolved are, where and when did the man contract the disease? What was its incubation? Where is the danger? Two nurses and mother and father were in close attendance. Dr. Miller attended the patient ten or twelve times and I visited him five times. We are all well at this date, August 21. The problems to solve are: First, what is the germ causing this disease? Second, how, by whom or in what way is the germ carried? Every suggestion by layman or physician should be reported and recorded. Every one who has had the disease should come forward and offer a little blood to help some one else.

Until the germ is isolated an exact serum cannot be made. Every facility for study with animals ought to be encouraged. Until the exact cause and method of contagion has been discovered we must resort to all known methods of quarantine and prevention and do many things which may later prove superfluous.

21 West 122d Street.

The Value of Deep Percussion in the Diagnosis of Subacute Intraabdominal Disease. — Neuhof refers to this procedure for the elicitation of localized tenderness, and states that it has been of great value in the diagnosis of subacute and subsiding intraabdominal affections, especially in the examination of obese individuals and of those who do not sufficiently relax their abdominal wall for satisfactory palpation. The method is free from danger and should therefore be made part of the routine physical examination in subacute and subsiding intraabdominal affections.—*Archives of Diagnosis.*

FUNCTIONAL PSYCHIC DISTURBANCES IN THE LIGHT OF WAR.

PSYCHIATRICAL problems receive their share of enlightenment from the vast laboratory the war has thrown open to medical science. Neuropathology and psychopathology are the subjects of much attention and discussion. Thus it comes to pass that modern theories in regard to the relation of psychic trauma and psychopathic predisposition are being distinctly advanced.

The observations made by Dr. Lewellys F. Barker in his presidential address delivered before the American Neurological Association in May, 1916, printed in full in the *Journal of Nervous and Mental Disease* for July, and in abstract in the MEDICAL RECORD of July 29, are confirmed by reports from the front, a number of which are published in abstract in the *Review of Neurology and Psychiatry* for May, 1916. There is an agreement of opinion that a distinction can assuredly be made between the psychotic or the psychoneurotic disturbance arising as the result of battle shock and that which is complicated by a psychopathic tendency, which only awaits, in order to become active, such extreme conditions and such excessive and untoward demands for adaptation as the exigencies of war present. Sudden and violent abnormalities in reaction are inevitable. Their occurrence, however, in no way denies the importance to be attached to the unconscious mental life in the production of mental disturbances. It does not argue for the current inflexible conception of pathological causes which attributes such phenomena always to the immediate traumatic agent.

It is noteworthy that these disturbances of mental equilibrium, inevitably induced and violent though they may be in character, are easily amenable to a wise therapy. The factor of chief significance in the consideration of the genetic theory of the functional neuroses and psychoses is the appearance and perhaps persistence of accompanying mental phenomena which seem to be aroused by the immediate traumatic outbreak and to follow in its train. Testimony points generally in this direction, that it is with the man who furnishes the fruitful soil, neuropathic or psychopathic, in whom these sequelæ are observed. The precipitating cause applies the spark to the unconscious material. The actual emotional importance of the immediate trauma manifests itself in the terrifying nature of the dreams of actual war experience. These, however, are transient phenomena. There are blended with these dreams, Dr. Bruce reports, quoting from the *Lancet*, "episodes utterly alien to the war" and events "in the patient's past history, the revivified emotions associated with which the war incidents have served to awaken, by stirring up similar emotions." One might expect some experience of horror to usurp consciousness and even to build up a permanent delusional system, which does happen at times unless an interpretative therapy comes to the rescue. Nevertheless, the deep-laid emotional experiences and sentiments which make up the personality, chiefly through the unconscious, by their self-assertion in the face of such crises, witness to the measure of their importance and reality.

The psychotherapy of the battlefields and hospitals is permeated with the modern comprehensive viewpoint and conditions there are met in the spirit which takes into account the whole psychical history, recognizes the remote contributing causes and believes in the value of the interpretative attitude toward the patient himself and in his psychic reeducation. It is striking to note in passing how frequently hypnosis is condemned as inadequate or actually deleterious. It is also of interest to observe how the demands of reality operate under war conditions to bring the patient back to his normal state, particularly in the acute transient conditions without the psychopathic background. This serves as an intensified illustration of the fundamental principle of psychoanalytic therapy. It is a radical application of the "reality principle" as the royal road to psychic health, a reality specially urgent and particularly effective amid the necessities of war.

Much of interest and much of value is thus afforded in the knowledge of mental disturbances, in the borderland cases as in the distinctively neurotic or pronounced psychotic conditions, and much is being added to the effectiveness of psychotherapy along these lines.

ERYSIPELAS TREATED WITH DIPHTHERIA SERUM

ABOUT two years ago Pollak recommended ordinary diphtheria antitoxin in the treatment of erysipelas and one year later Koller, a Swiss, briefly reported a case of his own in which he followed successfully the plan of Pollak. In the *Correspondenz Blatt für Schweizer Aertze* for July 8, Koller reports his second case. The patient was an old woman who was subject to attacks of facial erysipelas which had hitherto yielded to ichthyol applications. In the present attack ichthyol had been of no avail. After nearly all of the face and scalp had become involved, and the patient presented a high morning temperature, 3000 units of diphtheria antitoxin were injected. A remarkable decrease in swelling was very soon apparent and subjectively the patient was much better. By the end of twenty-four hours the swelling seemed to have disappeared, but as areas of tenderness remained in the scalp, 1000 more units of antitoxin were given. She was now objectively well, although probably by reason

of her age her general condition was somewhat grave, she being extremely weak, with insomnia and night sweats. At the end of five days she was discharged cured.

In comparing his two cases Koller finds several points of parallelism which show that the serum acts directly upon the cause of the disease. These refer to the sudden arrest and regression of the local process and a critical defervescence accompanied by profuse sweating. The second patient seemed doomed. Taken by themselves these two cases prove nothing, but taken in conjunction with Pollak's results they tend to corroborate the latter. The author apparently uses colloidal silver in the routine treatment of erysipelas and used it perfunctorily in the reported cases, but had never seen any constant improvement follow its use when given alone. It is possible, however, that the combination of serum and silver is superior to serum alone, and he would use both in severe cases or in the presence of special indications. He has seen cases in which a surprising improvement followed at once upon an intravenous injection of silver.

Koller's contribution is of great interest at the present time because ichthyol has practically disappeared from the market as a result of the war. The price of the very small reserve is prohibitive for the treatment of a malady like erysipelas, the importer's price being quoted at $16 a pound, and with the profit of the distributor and dispenser added the consumer might have to pay as much as 2 or 3 cents a grain. In hospital practice the normally high price of the drug has made it necessary to use cheaper applications when practicable, and in consequence it has never been possible to determine to what extent ichthyol is really a life-saving remedy. But deprived of it altogether public and private patients alike should be expected to suffer somewhat, and the serum treatment might to a certain extent offset the loss.

ARTIFICIAL PURIFICATION OF OYSTERS.

AN interesting series of experiments carried out by the Public Health Service (Public Health Reports, July 14, 1916) point to the economic possibilities of rendering oysters safe for human consumption. When it is considered that because of the abundant sources of food supply shell fish thrive very well in bays and estuaries polluted by sewage, it can be seen what prolific sources of infection they can be. Urban typhoid epidemics have often been traced to this source. And while the artificial purification of the oyster does not do away with the esthetic objections to eating an animal fattened in sewage it does eliminate the disease factor. The Rhode Island Fish Commission has placed the conditional limit of colon bacillus infection at 10 colon bacilli to the cubic centimeter. The usual infection with colon bacilli is many hundred per cubic centimeter.

It has long been known that there is a tendency to the self-purification of oysters when transferred to pure water. The self-purification is complete within from a few hours to two days. The modus operandi is evident when one realizes that the passage of water through the oyster is very large and very rapid. As much as 20 to 50 gallons of water pass through in a day. The passage of food particles through the intestinal tract is quite as rapid. In France basins of filtered water have long been used to effect this purification, but the cost of this process compared with the sale price of the oyster renders the method quite impracticable. And indeed, if it is fairly clean, unfiltered sea water is better for purification purposes because the food particles in unfiltered water stimulate passage through the intestinal tract and help to carry through and to discharge the contained colon bacilli.

Instead of filtered water, therefore, the usual methods of the chemical purification of water were utilized in these experiments to render the oysters free from colon infection. In carrying out these experiments oysters were inoculated with both free cultures of colon bacilli and attached colon bacilli; *i.e.* with the bacilli in finely divided agar suspension. The water was then disinfected with 10 per cent. calcium hypochlorite solution. A considerable purification of the oysters contained therein occurred within six hours, and a remarkable purification within twenty-four hours. The results were below the conditional amount permitted by the Rhode Island Fish commission, although the amount of the artificial infection was much greater than it would be in natural infections in polluted oyster beds. Usually two doses of hypochlorite were given, the second after six hours in order to reach such infection still within the oyster and not discharged because of the possible closure of the shell during the first period, and because of the rapid decomposition of the hypochlorite. This treatment was found not to have a bad effect upon the flavor of the oyster or upon its well-being. In the case of an element of food so widely used any method that will insure the safety of the consumer while preserving the flavor of the oyster is deserving of consideration.

THE FUNCTION OF THE THYROID.

OPINIONS with regard to the chief function of the thyroid differ considerably. Some believe that it governs metabolism, others that it is a vital antiseptic, and yet others that it is concerned with growth alone. In the *Medical Press* for June 7, 1916, Dr. Jos. Geike Cobb endeavors to answer these questions and gives a few facts and some theories dealing with the function of this gland. Firstly, then, the thyroid gland possesses the peculiar property—peculiar in the sense that it is not shared, so far as is known, by the other endocrine glands—of being able to store its secretion. This is proven by the fact that in cases where the gland has atrophied or been removed, its secretion can be replaced by artificial ingestion. As Dale says, we quite naturally turn to the colloid as being the stored up secretion, and, indeed, are justified in doing so, as there is evidence to show that this substance arises in droplets in the epithelial cells lining the vesicles. Again, this secretion contains a relatively large percentage of iodine, and on this fact, or partly on this fact, has arisen the theory that the thyroid has a phagocytic or antitoxic action. In fact, there are a tangle of theories concerning the action of the thyroid, some of which seem to give grounds for belief that its action is in a certain direction.

However, it is definitely known concerning the thyroid that a train of symptoms follows its deficiency or absence, whether produced experimentally on arising spontaneously, and that these symptoms will yield to thyroid feeding. Thyroid is, therefore, concerned with the growth of bone, with the development of the body, and with a normal circulation. Further, in the adult, there is now no doubt that absence or diminution of the secretion produces, or helps to produce, a condition of secondary anemia. Whether this argues any direct connection with the hematopoietic system it is at present impossible to say. That the thyroid is a direct circulatory stimulant there is no doubt; for the slow pulse, cold extremities, sluggish circulation, and deficient action of the sweat glands in submyxedema are very well recognized. The interaction of the thyroid with the other ductless glands will probably show that the relation between the thyroid and some of the other endocrine glands, notably the spleen, is a close one.

Volhynia Fever.

At a session of the Berlin Medical Society last February (*Berliner klinische Wochenschrift*, March 20) a new fever was described by His, Jungmann, and others. It has been studied in the German armies on the Eastern front, and bears considerable resemblance to malaria. The febrile crisis comes on suddenly and lasts one day, but from four to six days elapse before a second crisis. The pains are severe, especially in the lower limbs, and the shins may be very tender to pressure. The patient feels most wretched. The Polish physicians have looked on the ailment as a form of malaria or of relapsing fever, according to circumstances, but the Germans regard it as a third disease to be known as febris volhynica. The cyclical course suggests a protozoan cause, probably carried by an insect, and its incidence—mass infection in hospital patients—suggests that the latter is the louse. A study of the blood by Töpfer with dark illumination has shown the presence of a motile spirochete, but a short bacillus with clumping tendencies may have to be excluded as a cause. Jungmann has recognized the presence of organisms which resemble diplobacilli, and are constant in the blood of fever cases. These are in a high degree motile, and show considerable variety in form. No attempts at cultures were made, but by injecting the warm fresh blood into the tissues of guinea pigs febrile paroxysms were set up. The suffering caused by the disease is intense, and apparently the pains in the legs and back are as bad as those of any other infection. No mortality or permanent disability has been noted. The disease appears to vanish spontaneously in time. Tenderness of the shins persists longer than any other symptom. Russian prisoners knew of the disease but had no name for it. Their physicians prescribed quinine with benefit, but the Germans found the remedy inert.

A General Indication for the Use of Thiosinamine.

Patience and persistence in the use of a remedy along the line of a definite general indication often yields striking clinical results. Thus Dr. Gonzáles Castro reports in *El Siglo Medico* for June 24 that for four years he has been steadily employing thiosinamine and believes that it is especially indicated in imperfect or defective resolution in wound healing and inflammation. In one case an old man with some prostatic hypertrophy had developed gonorrhea five months previously and had eventually sought relief for complete retention. The stenosis was evidently due in part to abuse of injections of nitrate of silver, which had produced several wide strictures. While it was possible to empty and treat the bladder and secure some improvement by progressive dilatation, the author nevertheless made use of thiosinamine by subcutaneous injection. The rapidity in improvement could not have been accounted for by dilatation only, for within a brief interval the author passed gradually from a No. 8 to No. 24 and the patient's recovery was apparently complete after treatment for thirteen days only. Another case was one of traumatism of an eye which resulted in a large corneal ulcer and hypopyon. The cornea was opened and the pus evacuated. The development of a large leucoma was almost certain, but the author instilled into the conjunctiva a mixture of cocaine and thiosinamine and the result was a perfect recovery, not a trace of corneal opacity having developed. These successes are not isolated, but represent only a small part of a series of favorable results from this remedy in the author's experience.

News of the Week.

Poliomyelitis Situation.—The hoped-for decrease in the new cases of poliomyelitis in New York has not yet been apparent, 7,446 cases in all having been reported up to August 23, with 1,731 deaths. In Brooklyn and Richmond the epidemic appears to be "burning itself out," however, and in Manhattan there was a slight drop in the number of new cases for a few days. In the city as a whole 912 new cases were reported in the week ending July 29, 1,117 in that ending August 5, 1,151 in that ending August 12, and 912 again in that ending August 19. It is feared that with the close of vacations numbers of susceptible children not before exposed may return to the city, and that the epidemic may have a temporary flare-up. The date of reopening the schools in the city has not been definitely determined, but is probable that they will open as usual on September 11. At Princeton University, however, it has been decided to defer the opening to October 10.

In the State outside of New York City 1,239 cases were reported up to August 20, with 150 deaths.

For the purpose of securing an additional supply of immune serum a citizens' committee has been formed; this committee will endeavor to get in touch with the 700 or more persons here known to have recovered from poliomyelitis and will ask that they give blood. A fund of $2,000 has been raised to defray the expenses of the work.

The Committee on After-Care of Infantile Paralysis has selected the visiting nurses of the Henry Street Settlement to follow up all paralyzed patients in Manhattan and the Bronx, each patient being reported to the Settlement as soon as released from quarantine by the Department of Health.

Conference on Poliomyelitis.—The conference of State health officers and representatives of the Public Health Service held in Washington on August 17 and 18, adopted a report containing a

set of rules intended to check the interstate spread of the disease. As a first step, the report states, the situation should be put in the hands of the Public Health Service. The service should then undertake an investigation of the infected area, should make notification of the removal of persons under 16 years of age from an infected area to another State, and should issue permits for travel based on inspection by agents of the service, not on the certificates of private physicians. The report disapproved of quarantine by one State against another, or by one community against another in the same State; it was thought that the Public Health Service could perform all the duties of notification and certification required in interstate relations in case of unusual prevalence of poliomyelitis, and that State Health authorities should perform like services between communities in the same State. The report recommends, further, that all cases of poliomyelitis be reported immediately to the local and the State health authorities, and by the latter to the Public Health Service; that all persons 16 years of age or under moving from an infected area be kept under medical observation for at least two weeks; that the period of isolation of a case of poliomyelitis be not less than six weeks from the date of onset; that persons suffering from the disease and their attendants should be rigidly isolated in a properly screened room, all bodily excretions to be disinfected at the bedside, it being understood that removal of a patient to a hospital is greatly to be preferred to isolation at home; that in case of death from poliomyelitis the funeral should be strictly private; that wherever the disease is unusually prevalent assemblages of children in public places should be prohibited, and that schools should not be open without thorough medical supervision; that because of the existence of unknown carriers of the virus, measures should be taken to prevent contamination by human excretions, to suppress the fly nuisance, and to do away with the common drinking cup; and that a general educational campaign for cleanliness and sanitation, with particular instruction concerning personal hygiene, especially of the mouth and nose, be carried out. The report states that the epidemic prevalence at this time in certain States indicates a likelihood of epidemic prevalence next year in States not now affected, and it is, therefore, believed that the measures recommended should be continued in operation at least until such time as the incidence of the disease has subsided to or below its usual level.

Gift to Dental School.—Columbia University has recently received from Mr. James N. Jarvie a gift of $100,000 for the new dental school to be connected with the university, for which an endowment of $1,000,000 is being sought. It is now expected that the school will open in September in a temporary building near the College of Physicians and Surgeons.

Painless and Shockless Childbirth.—In the article with this title by Dr. Kapp in the MEDICAL RECORD of August 5, in one of the case reports the dose of heroine given was said to have been gr. ½; it should have been, as stated elsewhere in the article, gr. 1/12.

Quinine in Poliomyelitis.—Dr. N. McL. Whittaker of Brooklyn recommends an intramuscular injection of 10 to 20 grains of quinine and urea hydrochloride, followed by 3 or 4 grains of quinine per os every hour or so until the patient has received 40 grains or until evidences of quinine poisoning appear. He also recommends quinine in 2 to 5 grain doses every night as a prophylactic.

American Chemical Society.—At the meeting of the American Chemical Society to be held in New York on September 25 to 30, there will be conducted a symposium on occupational diseases, presided over by Prof. Charles Baskerville of the College of the City of New York. Among the subjects to be considered are the chemical trades, prophylaxis in chemical industry, diseases incidental to work in aniline and other coal-tar products, cedar lumber, mines, and explosives. The discussion will be participated in by a number of the leading authorities of the country.

Public Health Service.—As recently announced, Congress has made an appropriation for thirty-three additional assistant surgeons in the United States Public Health Service, and examinations will shortly be held in various cities for the convenience of candidates. Information as to these examinations may be obtained from the Surgeon General, United States Public Health Service, Washington. The tenure of office in these positions is permanent, and successful candidates will receive commissions immediately. After four years' service, assistant surgeons are entitled to examination for promotion to the grade of passed assistant surgeon, and in turn to the grade of surgeon. Assistant surgeons receive $2,000; passed assistant surgeons, $2,400; surgeons, $3,000; senior surgeons, $3,500, and assistant surgeon generals, $4,000 a year, and all grades receive longevity pay, 10 per cent. in addition to the regular salary for every five years up to 40 per cent. after twenty years' service.

Red Cross Preparedness.—As a result of its campaign the membership of the American Red Cross increased, during the six months ending July 31, 1916, from about 27,000, which represented the growth of the society for the past ten years, to about 210,000. During the same period the number of Red Cross chapters increased from 110 to 199. While up to six months ago practically nothing had been done towards organizing volunteer aid for the sick and wounded of our army and navy, since that time the necessary staffs for twenty-five base hospitals for 500 beds each for the army have been enrolled; several naval base hospitals of about half the size are under preparation; funds for the purchase of equipment of sixteen of the twenty-five army base hospitals, amounting to $25,000 each, have been subscribed, and the purchase of this equipment has been begun, the material being stored so as to be ready for immediate use in case of need.

Old Hospital Wrecked.—A dispatch from Paris states that the Civil Hospital of Rheims, formerly the Abbey of the Church of St. Remy, which was recently destroyed by German artillery fire, was one of the finest edifices in the city. Although the building was almost entirely reconstructed in the eighteenth century, there remained in one portion a part of a primitive cloister, a perfectly preserved and magnificent specimen of the twelfth century. The linen room had contained a beautiful collection of tapestries, but these were recently removed to the museum in Paris.

Good Health of the Guard.—The report for the week of August 12 of the health of the men on the Texas border shows that the sick rate among the National Guard was only 1.21, while among the regulars it was 2.38.

Opportunity for the Study of Poliomyelitis.—There is at the present time a position open for a graduate physician in the poliomyelitis ward at Bellevue Hospital, New York, where he will receive board and lodging in the hospital during the period of his service, which would be a six months' term, which could be supplemented by a further period of six months if desired. Application should be made to the superintendent of the hospital, Dr. George D. O'Hanlon. Preference would be given to applicants having previous hospital experience, but the latter is not necessary.

Opportunities in Civil Service.—The New York State Civil Service Commission calls attention to the opportunities offered to qualified physicians for appointment to positions in the medical service in State hospitals, prisons, and charitable institutions. Although the salaries offered seem to afford adequate compensation, the number passing the examinations has not been sufficient to meet the needs of the service. For instance, at a recent examination for prison physician, salary $2,000, the number of applicants was small and no one passed the examination successfully; an examination held at the same time for assistant prison physician, salary $1,500, produced only two eligibles. On examination for assistant physician in the State Hospital held on January 22, 1916, produced eighteen eligibles, but the list was practically exhausted by July 1. In the opinion of the commission the State Hospital Service really offers a career, as there is a regular line of promotion for the medical staff from assistant physician to superintendent.

Philadelphia General Hospital.—Dr. Richard C. Norris has resigned as visiting obstetrician to the hospital, and has been appointed consulting obstetrician. Dr. Edward A. Schumann has been made visiting obstetrician.

Red Cross Shipments.—The American Red Cross announces that from April 1 to July 1, 1916, 217 shipments consisting of 32,605 packages and having a total value of $1,002,021.87 were shipped to the Allied Powers, and that during the same period of 48 shipments, consisting of 6,667 packages and having a total value of $310,732.36 were shipped to the Central Powers. In addition, 34 cases of tetanus antitoxin, of a value of $131,986, were sent to Vienna, and 34 cases valued at $229,595.60 to Berlin; for these the American Red Cross was reimbursed by the Austrian and German Red Cross respectively. Smaller shipments, having a total value of $17,949.12, were also made to other countries, so that during this period the total value of the supplies shipped was $1,330,703.35. The total value of the supplies on hand on July 1 was $79,047.63.

Since October last, when the American Red Cross, owing to lack of funds, withdrew the hospital units it had established and maintained for more than a year in Europe, it has been endeavoring to obtain permission from Great Britain to send hospital supplies to the Central Powers. Great Britain now suggests, however, that the Red Cross reestablish the hospital units and promises to permit the passage of hospital supplies to these hospitals, and, in accordance with this suggestion, application has been made to the Central Powers, through the State Department, for permission for the reestablishment by the American Red Cross of one or two hospital units of six doctors and eight nurses each, in each of the countries. Germany, on the other hand, has recently announced that free passage of Red Cross supplies to other countries will no longer be allowed, and that German naval forces will receive orders to take such articles for their own use when they come within their reach.

American Association for Study and Prevention of Infant Mortality.—The seventh annual meeting of this society will be held in Milwaukee on October 19 to 21, 1916. The subjects to be discussed include governmental activities in relation to infant welfare, care available for mothers and babies in rural communities, standards for infant welfare, nursing, morbidity, and mortality in infancy from measles and pertussis, public school education for the prevention of infant mortality, and vital and school statistics. Dr. S. McC. Hamill of Philadelphia is president of the association, and Dr. William C. Woodward of Washington president-elect for 1917. Programs and further information may be obtained from the executive secretary of the association, 1211 Cathedral Street, Baltimore, Md.

Medical Society of the Missouri Valley.—Under the presidency of Dr. John P. Lord, the annual meeting of this society will be held at the Hotel Fontenelle, Omaha, Neb., on September 21 and 22, 1916. Particulars may be obtained from the secretary, Dr. Charles Wood Fassett, St. Joseph, Mo.

Obituary Notes.—Dr. JOHN ALVA MCCORKLE of Brooklyn, N. Y., professor of medicine in the Long Island College Hospital, died at the hospital on August 15, aged 69 years. Dr. McCorkle was graduated from the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1873, and a year later became associated with the chemical department of the Long Island College Hospital. In 1880 he was made professor of materia medica at the school, and in 1886 professor of medicine. For the past twelve years he had served as president of the College Hospital, and was also visiting physician to the hospital, consulting physician to the Kings County Hospital, the Norwegian Deaconess Hospital, the Jewish Hospital, and St. John's Hospital, and physician to the Long Island State Hospital. He was a member of the American Medical Association, the New York State and Kings County Medical societies, the Brooklyn Pathological Society, and the Academy of Medicine.

Dr. ADAM J. BLESSING of Albany, N. Y., a graduate of the Albany Medical College in 1886, and a member of the Medical Society of the State of New York and the Albany County Medical Society, died at his summer home in Sacandaga, N. Y., on August 6, aged 52 years.

Dr. WALDEMAR DORFMAN of New York, a graduate of the University of Berne, Switzerland, in 1882, died recently at his home.

Dr. HENRY COOLEDGE FROST of Buffalo, N. Y., a graduate of the Cleveland University of Medicine and Surgery, Cleveland, Ohio, in 1874, surgeon to the Homeopathic Hospital, and consulting surgeon to the County Hospital, died in Montreal, from heat prostration, on July 22, aged 56 years.

Dr. GEORGE WARREN BROWN of Winsted, Conn., a graduate of the Eclectic Medical of Maine, Lewiston, in 1883, died at his home, after a short illness, on August 2, aged 65 years.

Dr. JAMES H. LACKEY of Nashville, Tenn., a graduate of the Cincinnati College of Medicine and Surgery, Cincinnati, Ohio, in 1874, and a member of the Tennessee State Medical Association and the Nashville Academy of Medicine, died suddenly at his home, from neuralgia of the heart, on July 26, aged 68 years.

Correspondence.

THE TREATMENT OF POLIOMYELITIS.

To the Editor of the Medical Record:

Sir:—From recent observations and study of certain phases and aspects of the present epidemic of poliomyelitis I cannot resist the impulse of again calling the attention of the medical profession to the treatment of acute cases of poliomyelitis with a combination of quinine, phenacetin, antipyrine, and caffeine citrate in medicinal doses (as suggested in my previous communication in the *New York Medical Journal* of July 22 last), being fully confident that with this treatment, especially in the preparalytic stage, we are able to arrest the progress of the disease within twenty-four to forty-eight hours, and thus check or abort the advent of paralysis in perhaps 90 per cent. of cases. I am making this apparently bold statement with full appreciation of the danger of humiliation, in the event of an unprejudiced disproval of my statements, yet I do so fearlessly and without hesitation, being fully convinced of the efficacy and merit of the treatment.

The following prescription may serve to illustrate the dosage, vehicles, and mode of administration:

℞ Quinine sulphate,
Phenacetin,
Antipyrin, of each 20 grains.
Caffeine citrate, 4 grains.
Syr. yerba santa,
Syr. tolu,
Distilled water, of each equal parts to make 4 oz.

M. Sig.: One teaspoonful every two hours for children of about one to two years of age; in severe cases and somewhat older children, every hour till temperature, pain, muscular stiffness, and hyperesthesia disappear, then every two or three hours at the discretion of the physician. In children of from three to five years of age, the same prescription, but in doses about one-third larger. In children above that age, the doses may be modified at the discretion of the physician, but on no occasion will it be necessary to give more than 1¼ grains of each of the first three drugs, and not more than ¼ grain of caffeine per dose.

In case, however, some paralysis or muscular weakness should begin to manifest itself, which may happen, but very rarely, the administration of iodide of potassium with very small doses of Fowler's solution, in addition to the foregoing medicines, will soon effect a complete cure (provided the case is not of long standing). For instance, in the case of a two-year-old child:

℞ Potassium iodide, ½ dram.
Solution of pot. arsenite, 15 drops.
Comp. syrup of sarsaparilla.
Distilled water, of each 2 oz.

M. Sig.: A teaspoonful every three hours, the physician exercising his judgment as to older and younger children as the case may be.

I desire further to make a few remarks, and to submit certain prominent points and features in connection with the etiology and pathology of the present epidemic.

On close analysis of the various reports of the Health Department, as well as from my personal daily investigations and diligent study of everything that may be associated with the epidemic, I find very little, if any, proof or even fair evidence as to the existence of any relationship between the etiology of poliomyelitis and sanitary or hygienic conditions and surroundings. Nor are there any palpable data or strong enough indications as to the communicability or contagiousness of this affection. As a matter of fact, cases of poliomyelitis are found under all conditions and surroundings, irrespective of sanitary or hygienic standards. I have personally inspected houses and families where infantile paralysis had occurred and which I found in almost ideal sanitary and hygienic conditions; while on the other hand, I have visited dozens of houses with the most deplorable sanitary conditions with children actually bathing, as it were, in foul decomposing garbage and refuse in which not a single case of poliomyelitis has made its appearance.

Another noteworthy fact is to be found in the relative rarity of more than one case of the disease occurring in the same family or the same house. Children are developing the disease while apparently far removed from, and in no way in contact, direct or indirect, with any supposed source of infection. On the other hand, children coming in direct contact with patients seldom contract the disease.

A physician friend of mine who is an interne in one of the institutions with a large number of poliomyelitis cases (about 350) told me that they are keeping nonpoliomyelitic and healthy children together, and feeding them together, and have never noticed any evidence of contagion.

While far from depreciating the excellent and highly important precautions as to cleanliness, sanitation, and general hygiene, which are absolutely necessary for the prevention of all infectious and communicable diseases, and which it is the duty of every one of us to enforce to the best of our ability, I fail to see enough reason for extraordinary isolation and quarantine in this particular case.

In the face of the foregoing facts and phenomena it appears that the real factors which may be responsible as etiological agents in the present epidemic, are to be looked for in other directions, and in my opinion are to be found in some special atmospheric conditions, as temperature, humidity, atmospheric pressure, etc., which conditions are well known to be highly influential in predisposing to many pathological changes and organic lesions entirely independently of outside infections. Hence, why is it not possible that some special atmospheric conditions may set up, in susceptible individuals, a certain inflammatory process in the spinal cord?

B. Scheinkman, M.D.

152 Canal Street, New York.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

DYSENTERY—CASES FROM THE FRONT—NATURE AND DISTRIBUTION—SINGLE AND MULTIPLE INFECTIONS—COMPARISON OF MILITARY HOSPITAL TO POST-OFFICE—LAMBLIA INTESTINALIS.

London, July 29, 1916.

Drs. A. M. Kennedy and D. Rosewarne in the course of investigating cases of dysentery invalided home from Gallipoli found that the condition seemed to be due to infection by *Lamblia intestinalis;* in 12 cases they readily found this parasite. The persistence of the infection is a point illustrated by their cases. Previous observers have recorded a chronic dysenteric condition resisting all ordinary

treatment. Wenyon had three patients who maintained the infection for years. Some had repeated attacks accompanied by mucous diarrhea, but one of them showed no symptoms of intestinal trouble. The pathogenicity of the lamblia is not yet admitted as beyond question, so that a series of cases like these are of interest and may contribute to a decision of this point. The writers record their cases without making any dogmatic statement. They do not attempt to decide whether there had been a primary amebic dysentery on which a secondary infection had been planted. That is a question which may well interest bacteriologists who have the opportunity of investigating it. No positive agglutination was obtained with any of these patients' sera or with known dysenteric bacilli. If the organism be pathogenic, then how to deal with carriers becomes an important question. That they are not uncommon appears from the numbers found in the series under consideration—12 out of 136 consecutive cases of so-called dysentery—approximately 9 per cent.

The nature and distribution of the parasites in 1,305 dysenteric cases has been reported to the *Lancet* by Dr. Fantham, who took an active share in examining some 3,800 stools from soldiers in the hospitals of the western command. Most of the patients were convalescing. The parasites were mostly protozoa and *Blastocystis enterocolia*. Combined infections in 446 positive cases are stated. In single infections there were 325 cases; in double infections 79; in triple 33; quadruple 7; quintuple 2. Besides these, 499 examinations were made by Dr. Fantham of 14 special cases in the military hospital. All were parasitised and examined daily while in hospital. Most of them were specially examined for lamblia then for entameba. Double, triple, and other multiple infections were found in some of the stools: thus one patient showed when first seen *Girardia intestinalis* and *Antameba coli*. Soon spirochetes (eurygryata and blastocystis) appeared in his feces and later *E. histolica*. The periodicity of these cases was different. The lamblia decreased, disappeared for 13 days, then reappeared in sparse numbers; the spirochetes acted similarly in a shorter period. Tetramitus was also seen in this patient. Multiple infection was, however, rather rare. There are not so many parasites in a formed stool as in a diarrheic one. Relapses of lambliasis are met with. Some workers say the organism is harmless and give no treatment for it; and patients infected with it have been discharged from hospital as they had not dysenteric bacilli also, but they may carry the infective cysts of the parasite wherever they go and the danger of their setting up diarrhea is obvious. It is now commonly believed that amebic dysentery may be carried into a healthy district by an infected person who has no symptoms that trouble him, and the manner of preventing this is a problem demanding investigation.

At the Royal Society of Medicine Major Tate McKenzie compared a great military hospital to a general postoffice in which the patients were sorted out as first, second, and third class matter. The first was rapidly distributed to the Red Cross hospitals, but after treatment returned; the second had to stay a time at a convalescent hospital. Many of these found their way back to the front. For the third it was more difficult to provide either in hospital or homes. Early in the war they were sent from one depot to another. But later the director general arranged a series of command-depots to which were sent all cases for which there was a reasonable hope of cure within six months. The object was to return to the front those fit and to sort out and arrange for the others employment for which they were capable.

1. The Diagnosis and Management of Vasomotor Disturbances of the Upper Air Passages.—J. L. Goodale calls attention to the fact that in a large proportion of vasomotor diseases of the upper air passages the disturbances are dependent upon the entrance of a foreign proteid into the system. The method of entrance may be through the contact of the proteid in question with mucous membranes of the respiratory or gastrointestinal tract by inhalation or ingestion respectively. Foreign proteids may perhaps also develop in or upon these mucous membranes through autolysis of pathogenic or saprophytic bacteria. The application of the skin test to these conditions is of diagnostic value when employed with a recognition of the phylogenetic relationships of animals and plants, as determined by sero-biology. Proteid material for testing should be prepared both from the keratin and sera of domestic animals, from the pollen of the cheif causes of hay-fever, and from the various articles of food which enter commonly into the diet. Bacterial proteids derived from the various invaders of the respiratory tract should be available either in solution or in soluble form. When the skin reactions to the various classes of pollen proteids have been determined, the management of cases will depend largely upon the relative preponderance of the local reactions in relation to the clinical history. If the case is found to be seasonal, as in hay-fever, immunization treatment by injection of pollen extracts is likely to be of service but will probably have to be repeated annually. If the cause is perennial and is due to inhalation of foreign proteids, it is wiser to avoid the cause than to seek to effect a cure by immunization. If the disturbing proteid enters into the ordinary articles of diet, a tolerance may be gradually established by feeding the substance in progressively increasing doses. These investigations confirm the present methods of treating disturbances of bacterial origin, and emphasize the importance of draining regions which can retain the products of bacterial activity. Vaccine therapy in anaphylactic cases should be more accurately guided than in ordinary individuals. The writer concludes that we possess in the intelligent application of the skin test a very definite aid in the diagnosis and consequent management of cases of vasomotor disturbances of the upper air passages.

2. Asthma in Children. II. Its Relation to Anaphylaxis.—Fritz B. Talbot has followed forty-five cases of asthma in childhood over a period of several years and has studied twenty-three of these cases carefully; of these, eighteen had eczema at some time or other.

This is a higher proportion than was found by Berkhard. A family history of asthma, hay-fever, rose cold, eczema, or idiosyncrasy to some food was present in nineteen out of the twenty-three cases, while in the remaining four cases there were no notes in the family history on these points. In nineteen of the twenty-three cases there was a positive skin test to fresh egg albumen. Of the forty-five cases there were thirteen in which the skin test gave no clue to the etiological cause of the asthma. In one case thirty-eight tests were made before positive information was obtained; this illustrates the difficulty of finding the cause of asthma. It was found that one individual was apt to react to more than one form of protein. The essayist concludes that a definite etiological connection may be established between most cases of asthma and some foreign protein by the skin test. Information given by the skin test is of inestimable value in outlining the treatment of the case, and with the use of this information marked improvement or cure often follows. Experience has shown that when a positive skin test is obtained for a food and the food is then removed from the diet, the general condition of the patient almost invariably improves, and in many instances a cure results. It is still too early to say whether all of the positive reactions are of equal clinical importance, but experience seems to show that the severity of the symptoms is not always indicated by the size and character of the reaction.

4. Normal Reaction of the Skin to Stroking.—Edward A. Tracy describes what he believes is a normal reaction of the skin to a mechanical irritant because of the fact that it was observed in 1,165 out of 1,236 individuals examined. As there were known disease conditions present in the remaining cases, it strengthens the deduction that this reaction is normal. The phenomenon is that when the skin of a normal quiescent subject is stroked by a wooden instrument (a tongue depressor or a match) it reacts by a deepening of the skin tint, generally brief in duration, appearing where the stroke was made or in its immediate vicinity, and then, after a period of about fifteen seconds, by a longer lasting whitish color, showing itself in the location where the stroke was made. The writer gives his reasons for believing that this phenomenon is caused by a double nerve mechanism, one for vasodilation (autonomic) and one for vasoconstriction (sympathetic), together with at least two hormones in the blood stream, the hormone X (Eppinger and Hess' "autonomyn") activating the vasodilator mechanism, the other hormone, adrenalin (or analogue inciters of sympathetic nerve endings), activating the vasoconstriction nerve mechanism. The examination of a patient should include this test for the following reason: If the vasodilatation component alone is present we know that the hormone X, or analogues, is in excess in the blood, or that the hormone adrenalin (or pituitrin with analogous action) is in insufficient amount to activate the sympathetic nerve endings in the blood vessels tested. If the vasoconstriction component alone be present we know that the hormone adrenalin (or analogue) is present in excess in the blood, or the hormone X, or analogues, is present in insufficient quantity to activate the autonomic fibrils in the blood vessels.

5. Protein Extracts in States of Hypersensitization.—Horace M. Baker and Cleaveland Floyd point out the defects in the methods at present in use of preparing protein extracts and find the following method equally applicable to both food and bacterial preparations. The material to be used is secured in large quantities and suspended in normal salt solution and 0.5 per cent. phenol added. A bacterial suspension is autolyzed at a temperature of 48° C. for twenty-four to seventy-two hours, depending upon the organism. The suspension, immediately following the period of autolyzation, is quickly evaporated to dryness by a constant temperature of 40° C., thus favoring the reduction of the protein to a soluble form. To carry out this step the suspension is placed in a flat-bottom glass dish over a water bath, with an air current from an electric fan directed over the suspension. The flame under the water is protected by a shield to prevent variations of temperature. By this simple device the temperature remains constant and the quick evaporation to dryness is obtained. For testing purposes the powdered extract is ground up with glycerine in the proportion of 10 mg. of the powder to 1 c.c. of glycerine. One or two drops of this preparation are used for the test, which is carried out in a way similar to the von Pirquet tuberculin test.

8. Gonorrhea and Its Complications. A. Hyman.

1. The Story of Dementia Præcox.—Francis X. Dercum says that briefly put the story of dementia præcox begins with an impaired germ plasm. It deals with an organism defective and deviate in its development, a quality which involves the nervous system as well as other structures. In the course of its development the organism becomes toxic through a metabolic breakdown as a result of the mere strain of living. The cortex, already feeble and with diminished resistance, becomes a prey alike to exhaustion and intoxication, and the subsequent course is one of deterioration, the final chapter of which is dementia. Under circumstances like these it is not surprising that the clinical picture should vary greatly. This accounts for the tendency to separate out of the great mass of cases special forms, as is illustrated in the eighth edition of Kraepelin's *Psychiatrie*, in which no less than eight forms are differentiated. The writer ventures the prediction that the original classification into the hebephrenic, catatonic, and paranoid forms as presented in Kraepelin's original generalizations, modified, it may be, by subdivisions, is the one that will survive. He believes also that Kraepelin has gone too far in embracing, under the generalization of dementia præcox, the hallucinatory paranoid states of the adult. Purposes of study and clinical distinction are best served by limiting the conception of dementia præcox to the endogenous deteriorations of adolescence. For the adult form the term hallucinatory paranoia is much preferable. The writer further believes that Kraepelin is wrong in separating so widely the lucid paranoia of the adults, i.e. the paranoia simplex of Ziehan, the paranoia chronica of Siemerling, the *Verrücktheit* of Westphal and Sander, the *délires systématises des dégémérés* of Magnan from the other paranoid forms. In concluding he objects to the word schizophrenia, which Bleuler has devised and proposed as a substitute for the name dementia præcox, as not distinctive, and expresses the hope that it will not survive.

3. Our American Voice and Articulation.—Charles Prevost Grayson feels sure that no amount or depth of patriotism can anesthetize our ears that they will find anything musical in the voice of the average American, male or female, particularly female. He thinks

that those who are self-appointed custodians of the larynx and its vocal function, and of every nerve and muscle that plays a part in articulation, should assume a responsibility in correcting this national defect. They should all unite in saying that vocal instruction should be introduced and made an essential part of the curriculum of every school, public or private; that every child should be taught not only how to use his voice correctly but that he should be marked as rigidly for his proficiency or his lack as he is for any other of his studies. This instruction should be continued through high school, college, and university, and should include distinct enunciation as well as correct pronunciation. He urges that it is a part of the duty of each individual laryngologist to help bring about this innovation. It is but a commonplace to say that nothing so promotes the health and functional vigor of the larynx as cultivation of either the speaking or the singing voice. In all probability there is scarcely a day that each laryngologist does not warn one or more of his patients of the injury they are inflicting on their throats by some more or less glaring misuse of the voice. How much better would it be to render such warning entirely unnecessary by beginning the prophylaxis of the laryngeal trouble and the conservation of the human voice before harm has been done and bad vocal habits have been formed?

5. **Health Insurance from the Viewpoint of the Physician.**—A. C. Burnham discusses the more salient abuses occurring in the administration of the benefits of health insurance, and suggests solutions for a few of the problems that may arise. He believes that the systematic care of the industrial population on a large scale can be accomplished only by means of State control through a department modeled somewhat along the lines of the medical department of the United States Army, having hospitals, full-time medical officers, nurses, and other necessary medical employees. He outlines the plan as follows: The State would be divided into districts, and a medical unit having full care of the insured would be assigned to each district, the insured being directed for treatment to the headquarters of the unit having charge of the territory in which he lives. Specialists would be in attendance at certain hours and on call when required. Regular attendance upon the patients would be assured, the physician being sent from the medical center upon request. The clerical work would be done at the various centers by lay employees. If in such a system the salaries were made large enough, permanency of position was assured, and opportunity for advancement permitted, many physicians would be eager to choose just such a career. This system would, as a rule, assure quicker convalescence and more scientific treatment for the injured, pleasanter and more satisfactory work for the physician, and cheaper and better results for the State. Finally the author urges that if we are to have health insurance, and if we are to hope to benefit by the mistakes of others, this subject should be kept before the profession and thoroughly discussed before the Health Insurance act is passed—not afterward.

7. **Hereditary Chorea.**—Clarence King describes the principal features of this condition and calls attention to an observation made by H. O. Waters, who was one of the first men in this country to write upon this subject, which seems to have escaped the notice of other writers. This authority recorded that in one of his patients the movements ceased temporarily under the influence of all kinds of instrumental music except that from a common jewsharp. The writer refers to a case coming under his observation and previously reported in which the soft tones of a church organ had a remarkably quieting effect which lasted about an hour. He now reports another case in which the music of a violin had a quieting effect upon the patient, so much so that it became a regular practice for a fellow patient to play a few strains of music before he attempted to eat his meals. It was not uncommon for him to throw himself from bed or nearly so unless soothed by music. The questions arise whether in some of these patients there may not be an idiosyncrasy by which pathological stimulation of the nerve tracts leading to involuntary twitchings of the muscle fibers is interrupted or held back by psychic means for a time, or the inhibitory action of the sympathetic stimulated in the same way that intense fear or anger deadens pain. These cases suggest the possibility that music may be made a more valuable therapeutic measure than has been supposed, possibly ranking with, or even higher than, suggestion or hypnotism.

8. **Gonorrhea and Its Complications.**—A. Hyman reports a series of twenty-five cases of gonorrhea and its complications treated with the vaccine of Nicolle and Blaizot. During the period of vaccine treatment local therapy was withheld. Seven of the cases were definitely cured by the vaccine. Cases of uncomplicated acute or chronic urethritis were not influenced by the treatment. Cases of epididymitis were only slightly improved. Cases of chronic prostatitis showed the highest percentage of cures. Rather marked improvement followed the treatment in a few cases of gonorrheal rheumatism. From this experience it may be concluded that the atoxic gonococcus vaccine, although occasionally followed by a brilliant result, is most inconstant in its effects. It cannot be relied upon for a satisfactory result in any given case. The results in some of the cases justify further experimentation with the vaccine of Nicolle and Blaizot.

1. **The Nervous System As Influenced by High Altitudes.**—George A. Moleen refers to the general belief that "nervousness" is a result of living at high altitudes which has been accepted by the public, and in no little part by the profession, without inquiry as to the reason for the manifestations commonly grouped under the term "nervousness." An investigation of this subject shows that neurasthenia does not occur more frequently at high altitudes than at lower ones, because the general standard of living is better than in the more congested centers of population; the confined artificially lighted indoor workers are less common; there is a greater average of bright, cloudless days, and lastly, there is a greater intensity or actinism of the light. It is the class of patients who are able to live with more comfort at the lower altitudes and who manifest

irritable neurotic disorders repeatedly on going to higher elevations that prompted this investigation as a result of which it may be concluded that the demand for oxygen carrying elements of the blood increases directly with the altitude. In normal individuals this requirement is met through an increase in the red blood corpuscles and hemoglobin in from three to five weeks. This is normal acclimatization. This power of adaptation is diminished or wanting in certain individuals and results in oxygen want or anemia. As a result of diminished or limited oxygen supply, the increased excitability or irritability of the nerve structures may be explained. If by therapeutic or other means the blood-forming mechanism can be stimulated into activity, individuals should find no more difficulty in living tranquil lives in the high altitudes than at the sea-levels.

2. **Complications and Sequelæ of the Operation for Inguinal Hernia.**—Lincoln Davis presents an analysis of 1500 consecutive cases of inguinal hernia operated upon at the Massachusetts General Hospital from October, 1908, to December, 1914. In the 1500 cases there was a total of 1,756 operations, counting double hernia as two operations. In the male cases, numbering 1,388, the Bassini technique was employed 834 times, the Ferguson 764, and Halsted 15, with 24 cases of varying and miscellaneous technique. In 88 cases the hernia was direct; in others indirect. No cases of strangulated hernia were included. In 10 cases the hernia was of enormous size. In 69 cases the hernia was complicated by undescended testicle. There were 9 cases in which the bladder was contained within the sac. The appendix was found within the sac eight times, and removed in the course of the operations 46 times. There were 7 cases of sliding hernia. There was hydrocele present in 40 cases, marked varicocele in 26 cases. In 50 cases there had been a previous operation for hernia with recurrence. The anesthesia was general in 1,319 cases. Non-fatal postoperative complications of more or less severity developed in 438 cases, or 28 per cent.; some of these were trivial. In many cases the complications were multiple. Among the complications were sepsis in 178 cases; hematoma in 112 cases; affections of the respiratory tract in 138, and many miscellaneous complications, as otitis media, cholangeitis, persistent hiccough, phlebitis, acidosis, pyelitis, and mental symptoms. In summing up the writer states that the results of operation are on the whole good. The operation has a definite though low mortality rate (in this series 0.53 per cent.) and should not be undertaken on the old and infirm without good reason. Postoperative cough, hematoma, and sepsis are important factors in the incidence of recurrence, but the latter seems to play a lesser rôle than is generally assigned to it. A strikingly large number of patients anatomically cured complain of pain, probably due to nerve traumatism. General anesthesia is still best in the routine cases. Spinal anesthesia, on account of its greater danger and serious sequelæ, should have little place in this operation. Local anesthesia has a wide application in cases in which inhalation anesthesia is contraindicated, but carries a slightly greater risk of sepsis.

3. **The Prevention of Obstruction of the Passage of Gas.**—A. J. Ochsner. (See MEDICAL RECORD, July 8, 1916, page 82.)

4. **The Superiority of the Right Side Anus.**—John Young Brown. (See MEDICAL RECORD, July 8, 1916, page 82.)

5. **Lipectomy and Umbilical Hernia.**—Walter Lathrop. (See MEDICAL RECORD, July 8, 1916, page 86.)

6. **The Action of Various "Female" Remedies on the Excised Uterus of the Guinea-Pig.**—J. D. Pilcher, W. R. Delzell and G. E. Burman make a report on their investigations of this subject undertaken at the suggestion of the Therapeutic Research Committee of the American Medical Association. They have found that when the contractions of the uterus were altered the tendency was always toward a reduction in the amplitude of the excursions; in no instance did a drug appreciably increase the excursions. The following drugs lessened the amplitude of the excursions: *Aletris farinosa, Pulsatilla pratensis, Ichthyomethia piscipula, Scrophularia nodosa;* somewhat less active were *Valeriana officinalis* and *Cypripedium pubescens;* the drugs possessing very weak action were *Dioscorea villosa, Senecio aurcus* and *Scutellaria lateriflora.* A large number of drugs were found to be entirely inactive; among these were *Viburnum prunifolium, Viburnum opulus, Mitchella repens, Castanea dentata, Chamælirium luteum, Passiflora incarnata, Cnicus benedictus, Silybum marianum* and *Leonurus cardiaca.* The work shows that the domestic use of teas made from these drugs for any supposed action on the uterus is quite irrational, for water either extracts but a very small part of any of the active principles of the drugs, or, in the majority of them, none at all. These investigators conclude that not only are the drugs in this list unimportant, but that they are practically worthless. Their use is harmful as well as futile, since it tends to perpetuate therapeutic fallacies.

7. **Operative Treatment for Threatened Gangrene of the Foot.**—J. Shelton Horsley. (See MEDICAL RECORD, July 1, 1916, page 35.)

8. **Tuberculosis of the Cervical Lymphatics: A Study of Six Hundred and Eighty-seven Cases.**—Charles N. Dowd. (See MEDICAL RECORD, June 17, 1916, page 1112.)

11. **Intraspinal Injections of Magnesium Sulphate in Delirium Tremens.**—Edward A. Leonard makes this preliminary study based on his experiences with 12 cases in which lumbar puncture was performed, the amounts of cerebrospinal fluid removed varying from 10 to 40 c.c. After removal of the cerebrospinal fluid a cubic centimeter for every 25 pounds of body weight of a 25 per cent. solution of magnesium sulphate, at a temperature from 95 to 100° F., was introduced through the lumbar puncture needle into the canal. There were ten recoveries and two deaths in the series.

There is a rapid subsidence of the delirium and restlessness, and a restoration to normal within twenty-four hours, following this treatment; it is certainly of value in view of the little good sedatives do and the high mortality among these cases.

6. The Treatment of Hemorrhoids by Interstitial Injection. T. Bird.
7. An Unusual Case of Albuminuria. O. Leyton.

1. **An Inquiry into the Cardiac Disability of Soldiers on Active Service.**—John Parklinson records the results of an inquiry into the various conditions which lead men on active service to report sick with symptoms suggesting heart disease. It is based on 90 unselected cases passing through a casualty clearing station in France. Among these 90 cases valvular disease was present in 28. In 16 cases there was a history of acute rheumatism; in 18 the chief symptom was shortness of breath; in 8 it was pain; all cases with pain had also

shortness of breath. Palpitation was an additional symptom in one-half the cases. The symptoms were provoked by doubling and marching, and in 25 cases they had been present before enlistment. There were in this series 40 cases of so-called "soldier's heart," which the writer considers more in detail, and in commenting on these he states that among soldiers in training and on active service are found a number who report sick for cardiac symptoms on exertion, but show none of the physical signs indicative of heart disease. These men are the subjects of a cardiac disability which is unmasked by the exertion required of a soldier. It is not a specific variety of heart disease, and needs no specific name. In about one-half the cases in this series the disability had been present to some extent in civil life, and was, therefore, not the result of military service. This relative cardiac inefficiency may be a sequel of acute rheumatism, dysentery, influenza, or other infection; the result of myocardial changes due to age, especially in soldiers over forty; it may be associated with nervous disorder, particularly where palpitation is a prominent symptom; it may be due to a heart endowed with limited efficiency, the individual having always been "short-winded." A simple exertion test, such as climbing 25 or 50 steps, reproduces the symptoms in these patients, and so furnishes valuable information on the functional efficiency of the heart. Some degree of myocardial disease is present in a number of cases to which the history of infection bears witness. The absence of abnormal physical signs in the heart of a soldier should not prevent his discharge from the army if, under training or on active service, he shows breathlessness and precordial pain whenever he undergoes exertion well borne by his fellows. In this series was one man of forty with a to-and-fro murmur at the aortic area, who had served 16 months with no symptoms whatever of aortic incompetence, the defect having been discovered at a chance examination.

2. **An Enteric-like Fever in the Anglo-Egyptian Sudan.**—Albert J. Chalmers and Norman Macdonald state that, in addition to the usual varieties of enteric fever, last year they came across a number of cases of an enteric-like fever which was not caused by the ordinary organisms, as shown by blood cultures, fecal cultures, and agglutination tests. They have isolated an organism from these cases, the cultural and biochemical reactions of which indicate that it belongs to the Typhoid-Colon group. This organism the authors have named the *B. khartoumensis*. They find that it can be differentiated from the more important members of the Colon Subgroup, and that it belongs to the Entericus Subgroup, which can be easily distinguished from the Typhoid-Colon Subgroups. They also show that it can be differentiated from other members of this subgroup. They therefore conclude that it is a distinct species, and describe it in detail. It failed to agglutinate with a colon specific serum of high titre, but it showed group reactions with high titre paratyphoid A and B specific sera. It is, therefore, related not merely to the Colon Subgroup, but to the Paratyphoid-Gaertner Subgroup, and the writers consider it, and possibly the whole Entericus Subgroup, to be connecting links between the two collections of organisms.

5. **The Radical Treatment of Gastric Ulcer.**—Joseph Cunning states that gastrojejunostomy has fallen into disrepute because it frequently fails to relieve the symptoms, because it is sometimes performed upon pre-operative diagnosis of ulcer, when the real cause of the symptoms lies elsewhere, and because it may add to the patient's former troubles bilious vomiting or jejunal ulcer. His experience teaches that all gastric ulcers can be excised except those that are adherent to important structures in the neighborhood, and that gastrojejunostomy is useless for these. When the ulcer is adherent to important structures, the stomach can be detached from the base of the ulcer, the opening closed, and the base of the ulcer, after being scraped, and being now excluded from the stomach, will give no further trouble.

6. **The Treatment of Hemorrhoids by Interstitial Injection.**—T. Bird writes of this method of treatment of hemorrhoids, not because it is new, but because he thinks it does not receive the attention it deserves. It was used in this country by Hoyt some thirty years ago, and consists of equal parts of hazeline and distilled water, to which is added 10 per cent. of pure carbolic acid; the whole of the acid is not dissolved unless warmed. The bottle must be shaken, when the solution becomes turbid, and it is then ready for use. As much as 15 minims may be given at one sitting, though it is customary to begin with 3 minims. It usually requires eight or nine injections, at intervals of two days, to effect a cure. When this method is used, recurrences are very rare. Some cases in old people are better treated in this way than by cautery or incision.

6. Death After Nitrous Oxide-Oxygen and Local Anesthesia. W. J. McCardie.

1. **Industrial Diseases Prevailing among Iron and Steel Workers in Middlesbrough.**—J. Watkin Edwards quotes from the Supplement to the Sixty-fifth Annual Report of the Registrar General the statement that in the iron and steel industry the mortality at every stage of life is above the standard for "Occupied and Retired Males." At every stage of life the death rate exceeds the average for metal workers generally, being 18 per cent. above the standard. This led the author to investigate conditions at Middlesbrough, where the manufacture of iron and steel is the chief industry. He finds that the death rate here for males between the ages of twenty-five and sixty-five is 40 per cent. higher than that of females. The diseases which caused the most deaths were organic heart disease, pulmonary tuberculosis, bronchitis, and pneumonia, the latter causing by far the largest number of deaths. The adverse influences which seem to be at work causing these diseases are: Working at high temperatures; long hours of work; fatigue; insufficient rest, sleep, and recreation; working at night; careless exposure to cold and wet; intemperance; inhalation of dust; inhalation of poisonous gases, such as CO; trauma. The death rate from pneumonia is between two and three times higher in Middlesbrough than in the country generally, and men engaged in the iron and steel industry are much more liable to it than others. In the majority of cases the disease seems to be conveyed by autoinfection, a condition of lowered resistance due to one or more of the above-mentioned causes furnishing the state of ill health favorable to the growth of the organism. As prophylactic measures special attention should be given to oral sepsis, enlarged and unhealthy tonsils and adenoids, indigestion, and constipation. In a general way, where work entails great effort and the full natural workday of 240 foot-tons is much exceeded, an eight-hour day should be the maximum demanded.

2. **Head Injuries in War.**—Augustus W. Addinsell states that they have been told that "practically always" depressed fracture of the inner table is accompanied by "a cone-shaped pulping of the underlying brain which acts as an immediate source of irritation to the surrounding brain, and therefore that an apparently wounded dura should be opened." He objects to this statement on the ground that the pulping of the brain tissue cannot be recognized before the dura is opened and that there is no evidence that softened brain tissue is a source of irritation or is beyond recovery. Therefore, in those cases in which he has removed pieces of depressed bone and foreign bodies and the dura has been intact he has not opened it. His experience has embraced thirty-seven cases. The plan usually adopted is to allow the patient complete rest for three or four days, unless the symptoms very urgently call for immediate interference. These cases show in general that a wound of the skull, however slight, should not be regarded too lightly. They also seem to show that when definite focal symptoms arise while the case is under careful observation they should be dealt with promptly if they be within the reach of legitimate surgery. In defense of his waiting policy the author states that all of the patients who have developed epileptiform seizures and paralysis while they have been in the hospital, and upon whom he has operated for depressed fragments of bone, have either recovered from their symptoms or improved, and in none have the symptoms returned prior to their transference to England. He rarely uses a drain inside the skull unless the wound of the brain is so deep as to give rise to grave risk of the destroyed and infected brain matter finding its way into the ventricles. Another practical point emphasized is in the matter of incision of the scalp. It is advisable nearly always to turn down a flap for the purpose of examining for bone injuries, which in a number of cases have been found to occur at some distance from the wound of entrance in the scalp, due to shell or schrapnel having pierced the scalp in an oblique direction.

3. **Notes on the Treatment of Hernia Cerebri.**—S. Smith records his experience at a base hospital where between six and seven hundred cases of gunshot wound of the head have passed through his hands. One of their most difficult problems was the prevention of, or, if that was impossible, the treatment of, hernia cerebri. As a means of diminishing the cerebral exposure they have found suture of the edges of the scalp wound after excision of the edges of the original wound only possible in a very small proportion of their cases. As an antiseptic lotion they have found a mixture consisting of equal parts of carbolic lotion (1 in 20), hydrogen peroxide (10 vols.), and water especially valuable. In cases in which hernia cerebri occurs, whether following operation or where no operation has been performed, the systematic use of lumbar puncture has proved of the utmost value. If after the first puncture the hernia shows no signs of decreasing and compression symptoms do not decrease, the tapping is repeated on alternate days until the pressure, as shown by the manometer readings, is brought down to within reasonable limits. The author describes his method of performing the lumbar puncture under general anesthesia, and emphasizes the importance of the sitting posture as a valuable auxiliary in the treatment of these cases.

5. **The Treatment of Chlorine Gas Poisoning by Venesection.**—A. Stuart Hebblethwaite gives a detailed account of thirty cases of chlorine gas poisoning upon whom venesection was performed and who lived. He states that venesection is not required for all cases. Two types of cases, which he calls the "cyanotic" and the "cardiac failures," require no bleeding. In order to be successful early venesection is necessary. It is performed by direct incision into the median cephalic or median basilic vein, the amount of blood extracted ranging from 15 to 25 c.c., depending upon the patient. The results in practice were relief of the cyanosis, relief of congestion in the lungs, relief of acute headache, and promotion of sleep. The theory upon which the treatment is based is that (a) the resistance of the heart is lowered in ratio to the amount of blood withdrawn and (b) the resulting abstraction of fluid from tissues to make up for the loss—and it is not unreasonable to suggest that this abstraction takes place from a place where fluid is in excess—that is, in the waterlogged lungs. This again would lead to a lessened resistance through the pulmonary system.

July, 1916.

Paludism and Quinine.—Job and Hirtzmann, after some laboratory research in a military hospital, conclude that the action of quinine upon the hematozoon is constant even amid variations. When the condition is a paludism of first onset without gametes in the blood—*i.e.* when the first manifestations of the disease date back only eight or ten days—an intensive quinine treatment maintained for three or four weeks will sterilize the body so that there will be no recurrence. After the gametes have appeared in the blood, quinine medication will suppress the anemia and in a general way the other manifestations of chronic paludism; but it must be kept up until the disappearance of splenomegaly and until the blood count is normal, as shown by repeated examinations. The authors have never seen the so-called quinine-resisting hematozoa. If there is any reason to believe that the drug is not absorbed in the intestine it may be given by hypodermic. During the first two days 1.5 grams are given in six doses, one every two hours. The dose is then reduced to 1 gram for the next four days. The patient has thus received 7 grams during one week. During the second week the patient takes a gram for five consecutive days, and during the third week the same dose for four consecutive days, then for three days, and so until cured. The results of giving quinine as a preventive are lacking in precision. At least half a gram daily should be used and the results may still be in doubt. Probably 1 gram given on two consecutive days each in one week will give better success.

A Certain Method of Differentiating Diphtheria Bacilli from Its Congeners.—Martin and Loiseau refer to cultivation of the diphtheria bacilli in Veillon tubes, in which the organisms proliferate throughout the medium. It was long ago noted that the Klebs-Loeffler bacillus is anærobic, while the microorganisms associated with it and resembling it are ærobic and flourish at the surface of the medium. The latter is classed as a peptonated, saccharated gelose. Two hundred and fifty cubic centimeters of minced veal are macerated in 500 c.c. of water and mixed with an equal portion of Martin peptone. To each liter of this mixture are added 8 grams gelose, 15 grams glucose, and 2 grams potassium nitrate. After solution add the white of one egg. Then heat at 115° C. for one hour and filter. Divide among sterile test tubes of the height of 10 or 12 cm. Sterilize again by heating at 100° C. for half an hour on three consecutive days. Begin with a pure culture. With a glass hook take a bit of colony

and place it in a tube containing 10 c.c. sterile bouillon. A little of this dilution should be slid down the side of the Veillon tube and the latter then shaken to scatter the microorganisms. The gelose in the tube should now be melted by boiling, then cooling rapidly to 50° F. Now add with a pipette 1 cm. of the bouillon dilution of bacilli to the length of the tube and mix carefully. Cool the tube and place it in the incubator. Often after fifteen hours we shall find colonies scattered uniformly throughout the tube without any predominance in the field of ærobiosis. The so-called Hoffman bacillus, on the other hand, while it behaves in the same manner in nonsweetened media, is quickly differentiated from the true diphtheria bacillus in the Veillon tube, in which in from twenty-four to thirty-six hours it may be seen in the uppermost centimeter of the tube, close to the surface. After some days standing colonies are seen growing luxuriantly on the surface of the medium, while the diphtheria bacillus remains unchanged beneath the surface. The term Hoffman's bacillus is synonymous with the pseudo-diphtheritic bacillus of writers.

Metastases Which Follow the Treatment of Tumors with Roentgen Rays and Radium.—Kirmisson contributed an article on this subject in the Bulletin for July 12, and following is the discussion: Bazy mentioned a case of lymphadenoma in the parotid region (diagnosis by biopsy). As it was deemed inoperable, a radium tube was inserted. This was six years ago, and the patient is now alive and well. Ten years ago a radiologist treated his wife for cancer of the cervix with *x*-rays, within and without. She, too, is living and well to-day. The case was a postoperative recurrence. Schwartz saw prompt improvement follow the use of radium on a ganglionary malignant tumor, but a fatal metastasis suddenly appeared at the base of the skull. He also cites a case of local recurrence after radium treatment and a pelvic recurrence of cancer of the uterus which was doing splendidly under radium treatment. But these cases are exceptional. Routier saw a remarkable cure of a lymphosarcoma of the tonsil under radium; on the other hand, a cancer three times removed seemed to relapse with unusual rapidity under radium treatment. Gaucher stated that even superficial cancers sometimes recur after radium and *x*-ray treatment. As is well known, both resources are at times able to cause cancer *de novo*. To offset such cases, Béclère, whose experience is immense, has cured with radiotherapy a number of deep-seated, inoperable intraabdominal tumors. Thus in a case of a large metastasis to the spleen from a testicular tumor, with advanced cachexia, seven days' use of the tubes caused a rapid disappearance of the splenic growth with a gain of 24 kg. That was five years ago, and the patient is now fighting at the front!

July 27, 1916

Remote Results of Pleuro-Pulmonary Projectile Wounds.—Denechau sums up his experience as follows: There is a definite syndrome common in these results. In about one-half the victims an active life is possible—even a return to the ranks. The condition is amenable to treatment by respiratory gymnastics, but remote complications may supervene. These include pulmonary tuberculosis; while simple pleurisy may pursue a severe course with empyema, abscess, gangrene. Projectiles which remain in the thorax constitute a source of danger of infection, and should, if possible, be removed. The author has studied fifty cases. At first at least forty, or 80 per cent., seemed to have recovered in all respects. Examination, however, revealed the presence not only of functional but structural anomalies. The former comprised pain and dyspnea. Pain was constant at the site of the wounds, spontaneous but increased by cough, rapid exertion, yawning, etc. In sixteen out of forty dyspnea was severe enough to interfere with an active existence. In a number of cases the injury had evidently been responsible for tracheobronchial adenopathy. The *x*-ray also showed evidences in the wound track in nearly every case examined. In nineteen of the material the bullet was still in the thorax and in fourteen of these seemed to be well tolerated. In three a small cavity formed, which in one instance suppurated at recurring intervals. A fistula eventually formed. In this patient the ball was extracted and no more pus formed. In six other cases the ball was also extracted, but no details are given. In the entire series of seven cases there was no improvement followed in the functional anomalies.

Improved Tracheotomy in the Adults.—Luc believes that he has simplified the technique and cut short the duration of this operation. He is at present at the Val de Grace, where tracheotomy is often required in soldiers with laryngeal stenosis. Local anesthesia is always employed. The patient's throat is made prominent by placing a cushion under his shoulders, with head extended and supported by an aid. If, as often happens, the patient is in dyspnea, the latter elevates the head at each paroxysm. The operator should be at the left of the patient while giving the anesthetic (novocain-adrenalin). Five minutes are allowed for diffusion. The incision is begun at the upper border of the cricoid cartilage and its entire length is 5 cm. Retractors are then applied and the cartilage denuded, while the trachea is similarly exposed under the use of a grooved director. A special narrow retractor is now applied over the first ring of the trachea in the lower angle of the wound and pulled downward, fully exposing the passage. The bistoury is now plunged into the tracheal wall, the back of the instrument being against the retractor, and the rings are successively divided from below upward. The tracheotomy tube is now inserted and the small retractor withdrawn. A few clamps bring the lips of the wound together and hold them in apposition.

Excessive Fertility.—A correspondent calls attention to a remarkable case of fertility in an Italian woman of 40, residing not far from Pompeii. Up to date she had borne 56 children. She had given birth once to sextuplets and at least twice to quadruplets, while triplets had been born on a number of occasions. While some of these children had been born alive the mother had been unable to raise any of them with a single exception, that of the first born daughter. The ages at death and causes of death are not mentioned. The surviving child had been placed by the mother in a convent.—*Correspondenz-Blatt für Schweizer Aerzte.*

Dialysates.—The principle of Bürger of obtaining active principles of fresh plants by dialysis, which has recently attracted notice, is only a reintroduction of the principle of Golaz, who was the first to claim that dialysates are superior to extracts. Preparations made by Golaz's procedure have been in the market since 1896, and have been continuously in use, according to a letter from a correspondent who likes especially a dialysate of valerian which can often replace bromides, the cost of which is now excessive. Other dialysates may prove useful as substitutes for high priced drugs. The writer also likes the dialysates of digitalis and strophanthus. — *Correspondenz - Blatt für Schweizer Aerzte.*

Book Reviews.

THE TREATMENT OF INFANTILE PARALYSIS. By ROBERT W. LOVETT, M.D., Boston, John B. and Buckminster Brown Professor of Orthopedic Surgery, Harvard Medical School; Surgeon to the Children's Hospital, Boston; Surgeon-in-Chief to the Massachusetts Hospital School, Canton; Consulting Orthopedic Surgeon to the Boston Dispensary; Member of the American Orthopedic Association; Corresponding Member of the Royal Society of Physicians, Budapest; Korrespondierendes Mitglied der Deutschen Gesellschaft für Orthopadische Chirurgie, Socio della Società Italiana di Ortopedia. With 113 illustrations. Philadelphia: P. Blakiston's Son & Co., 1916.

COMING from the pen of so distinguished a surgeon who has devoted many years to the therapeutic as well as the surgical treatment of infantile paralysis this book needs but little comment except to recommend it heartily to the members of the medical profession who are desirous of the most approved up-to-date methods of combating the sinister results of this dread disease. Dr. Lovett himself says that since the great prevalence of infantile paralysis in America from 1907, our advance in knowledge of the affection and its treatment, especially on the therapeutic side, has been so rapid that it has not had time to find its way into the text-books, but exists almost wholly in the fugitive periodical literature. The book is a small one, containing but 161 pages. However, not a word is lost, as the explanations are remarkably clear and concise, almost elemental in their directness. To add to the clearness of text, the illustrations are clean-cut and well-produced. The author dwells at length on the subject of muscle training, because, as he says, all experienced surgeons are to-day agreed that the operative treatment of this disease should not be undertaken until at least two years after the onset, and during this time, when the most rapid progress is to be made, the treatment needs to be a non-operative one of which muscle training is the most important therapeutic measure. The text is divided into the treatment of the acute, convalescent, and chronic phases, operative treatment, muscle training, and the spring balance muscle test.

SURGERY IN WAR. By ALFRED HULL, F.R.C.S., Major Royal Army Medical Corps, Surgeon British Expeditionary Force; Late Lecturer on Surgical Pathology, Royal Army Medical Corps, Millbank; and Surgeon, Queen Alexander Military Hospital. With a Preface by Sir ALFRED KEOGH, K.C.B., M.D., Hon. Physician to H. M. the King; Director General Army Medical Service. With 26 Plates and 55 Text Figures. Price, $4.00. Philadelphia, Pa.: Blakiston's Son & Co., 1916.

THE surgical practice of the present war is in many respects novel; that is to say, the manner in which wounds should be treated has been, to some extent, revised as a result of the teaching of the present campaign. This is due partly to the character of the wounds brought about by modern implements and engines of destruction and partly to the unprecedented conditions under which war is being waged. Mr. Hull's book is the summary and conclusions of the surgical experiences of an able surgeon of the present campaign from its commencement up to the time when the book was written. The most interesting portion of the work is that which deals with the methods of treating sepsis. Sir Almroth Wright's work on the bacteriological side together with recent surgical developments have probably revolutionized measures of treating sepsis, although it must be borne in mind that by no means the last word has been said on the subject. The book by Hull, as well as being interesting in a high degree, is valuable in the existing state of affairs in this country.

MANUAL OF OPERATIVE SURGERY. By JOHN FAIRBAIRN BINNIE, A.M., C.M. (Aberdeen), F.A.C.S. Surgeon to the Christian Church, the German and the General Hospitals, Kansas City, Mo.; Fellow of the American Surgical Association; Membre de Société Internationale de Chirurgie and of the Western Surgical Association. Seventh edition, revised and enlarged. Price, $7.50 net. Philadelphia: P. Blakiston's Son & Co., 1916.

MOST books on operative surgery are written with one eye to the needs of the student and the other to those of the practising surgeon, the result often being a combination of elementary and advanced material satisfactory to neither. Binnie not only makes no bid for textbook honors, but specifically disclaims catering to undergraduate requirements. His book, therefore, is somewhat unique; for it is especially devoted to the unusual and difficult phases of the subject rather than to the typical and more or less commonplace. This does not mean that what might be called the normal surgery of the appendix, gallbladder, etc., has been neglected, but that more space has been devoted to the problem of dealing with complications which may be found or which may arise during the course of operation than is usual in other operative surgeries. In addition, much space has been given to such subjects as the surgery of the pituitary body, spleen, pancreas, heart, blood-vessels, and other organs and structures where surgery steps in comparatively rarely, or where there has been marked progress in surgical technique in recent years.

Some rather surprising omissions may be noted. Cushing's work in pituitary surgery is barely mentioned and his method of operating is not described, although Cushing has been sufficiently prominent in this field to warrant rather full reference to his work. In discussing the treatment of hydrocephalus I. S. Haynes' method of draining the cisterna magna certainly not only deserves mention, but detailed description and comment. In the section of blood transfusion it is surprising to find no reference to the Lewisohn-Weil citrate method. Much more successful clinical surgery of the heart has been done than the book seems to indicate. In the section on cervical tumors there is no mention of tumors of the carotid body, although Callison and McKenty reported one case and analyzed the reports of fifty-nine others from the literature in December, 1913, while we have noted reports of several others since then. While agreeing that section of the vagus "is not necessarily fatal," its danger should be emphasized rather than minimized, as was emphasized editorially in the MEDICAL RECORD for January 3 and 10, 1914. The value of the article on cervical rib would be much enhanced by utilization of the material contained in Henderson's report of thirty-one cases observed at the Mayo Clinic. While Fuller's method of seminal vesiculotomy is described and discussed, Binnie fails to mention that of Squier which represents a distinct advance in the surgery of precision.

Among minor criticisms we would note that iodoform in the form of powder, emulsion, or as iodoform-impregnated gauze is continuously and obtrusively recommended. Because of the danger of iodoform poisoning, if for no other reason, we feel that the indiscriminate use of iodoform gauze as a drainage material should be condemned. Finally we note that there are a great many typographical errors both in the text and in the otherwise excellent index.

AMERICAN PUBLIC HEALTH PROTECTION. By HENRY BIXBY HEMENWAY, A.M., M.D., author of the Legal Principles of Public Health Administration, etc. Price, $1.25. Indianapolis: The Bobbs-Merril Company, 1916.

THIS book has been written with the object of arousing the public to a sense of their selfish interest in efficient public health administration. With the view of thus arousing these instincts of self-preservation the work is dedicated to the Women of America as "the power behind the throne." Dr. Hemenway appears to have written a forcible little work which should aid in achieving his object.

THE SEX COMPLEX. A STUDY OF THE RELATIONSHIPS OF THE INTERNAL SECRETIONS TO THE FEMALE CHARACTERISTICS AND FUNCTIONS IN HEALTH AND DISEASE. By W. BLAIR BELL, B.S., M.D., London, Examiner in Gynecology and Obstetrics to the University of Belfast, and to the Royal College of Surgeons, England; Hunterian Professor of Royal College of Surgeons, England; Gynecological Surgeon to the Royal Infirmary, Liverpool, etc., etc. Price, $4.00. New York: William Wood & Company, 1916.

THIS new and important work on endocrinology should be read by all progressive physicians. The first section is devoted to the results on the female genitals and constitution of extirpation of the various endocrinic glands. This is necessarily based for the most part on animal experiment. The second section deals chiefly with human physiology and pathology—the results upon the uterus, ovaries, and secondary sexual characteristics of derangement of endocrinic functioning, the phenomena of puberty and the menopause, hermaphrodism, etc. While most of these facts in Part II are well known they are summed up and correlated in a logical and concise manner.

DIAGNOSTIC METHODS, Chemical, Bacteriological and Microscopical. A Textbook for Students and Practitioners. By RALPH W. WEBSTER, M.D., Ph.D., Assistant Professor of Pharmacological Therapeutics and Instructor in Medicine in Rush Medical College, University of Chicago; Director of Chicago Laboratory, Clinical and Analytical. Fifth edition. Price, $4.50 net. Philadelphia: P. Blakiston's Son & Co., 1916.

THIS work first appeared in 1907 and the appearance at this time of the fifth edition is one of the best testimonials to the value of the book. The frequency with which the editions have appeared have enabled the author to keep up with the times in the presentation of the numerous new methods which are appearing in such rapid succession. A large number of the newer methods have been added to this edition and the number of references has been generously augmented so that it is some twenty pages larger than the previous edition. It is also rather more attractively bound than the fourth edition was. The discussion is treated conservatively, but it is chiefly as a book of methods that the work is valuable. It can be unreservedly recommended.

CAMBRIDGE PUBLIC HEALTH SERIES. Under the Editorship of G. S. GRAHAM-SMITH, M.D., and J. E. PURVIS, M.A. POST-MORTEM METHODS. By J. MARTIN BEATTIE, M.A., M.D., Professor of Bacteriology, University of Liverpool. Formerly Joseph Hunter Professor of Pathology, University of Sheffield. Price, $3.25. Cambridge: The University Press; New York: C. P. Putnam's Sons, 1915.

THE present volume is the most recent addition to the excellent series of monographs on subjects relating to public health published by the Syndics of the Cambridge University Press. About one-half of the book is devoted to the general technique of autopsies and contains nothing strikingly different from what is said in most works on the subject. The second half is of especial interest, however, for it consists of a series of chapters on the diseases of the various systems and organs of the body, and on the more important diseases. Under syphilis or leukemia, for example, will be found enumerated all the evidences of those diseases that may be found after death, and in a similar way the other commoner conditions are discussed, as well as many tropical disorders. There are also useful sections on the bacteriological methods to be employed, on the recognition of cases of poisoning, and also on making autopsies on animals. The book is one that will be found useful by anyone engaged in post-mortem work, and contains a great amount of information in a very compact form.

A MANUAL OF SURGICAL ANESTHESIA. By H. BELLAMY GARDNER, M.R.C.S., L.R.C.P. London. Honorary Anesthetist to the King George Hospital; Formerly Anesthetist and Instructor in Anesthetics at Charing Cross Hospital; Anesthetist to St. Mark's Hospital for Fistula, The National Orthopedic Hospital and the Male Lock Hospital; Assistant Anesthetist to the Royal Dental Hospital of London. Second Edition. Octavo of 220 pages, with 8 plates and 36 illustrations. Price, $2.25. New York: William Wood and Company, 1916.

IN this book the subject of general anesthesia is taken up thoroughly and cardinal principles are strongly emphasized, both in connection with anesthesia in general and as applied to the administration of the various individual anesthetics, anesthetic mixtures, and sequences. Chapters are also included on spinal and intratracheal anesthesia, ether infusion, and anociassociation. The result is a very useful manual for the student or recent graduate who is about to begin his hospital interneship, or for the practitioner who has not had the benefit of such a training in administering anesthetics as is obtained by members of a hospital house staff. While this book is written with the idea of instructing in all the principles pertaining to the art of inducing safe general anesthesia, and while all pains have been taken to warn the practitioner of the pitfalls that are to be avoided if one is to bring the patient through the anesthesia successfully, the author recognizes the fact that no amount of book knowledge *alone* will make a successful anesthetist—that a man must have a certain amount of experience under direct, competent supervision. One who is thoroughly conversant with the teachings herein contained will be well equipped to profit by the practical clinical instruction that every doctor should receive before attempting to administer a general anesthetic on his own responsibility.

THE BASIS OF SYMPTOMS. The Principles of Clinical Pathology. By Dr. RUDOLPH KREHL, Professor and Director of the Medical Clinic in Heidelberg. Authorized Translation from the Seventh German Edition by ARTHUR FREDERIC BEIFELD, Ph.B., M.D., Instructor in Medicine, Northwestern University Medical School, Chicago. With an Introduction by A. W. HEWLETT, M.D., Professor of Internal Medicine, University of Michigan, Ann Arbor. Third American Edition. Price, $5. Philadelphia and London: J. B. Lippincott Company, 1916.

READERS who are familiar with the earlier editions of Krehl's classical work will find in the present translation of the latest German issue many important changes. In the first place, the new title more truly represents the scope of the book than the old, which now appears as a subtitle. There is much new material on such subjects as the disorders of heart action, especially in relation to rythm, on nephritis, the functional tests of the kidney and the significance of the non-protein nitrogen, on gastric secretion and motility, on the diseases of metabolism and the glands of internal secretion, and on questions of infection and resistance, etc. What is of especial importance is that the translator has added much material, incorporating the work of American investigators, which has not been sufficiently recognized in the German text. The editorial notes so introduced are numerous and add greatly to the value of the book, which is unique in the field covered and should certainly be read by every student of medicine.

STUDIES IN SURGICAL PATHOLOGICAL PHYSIOLOGY FROM THE LABORATORY OF SURGICAL RESEARCH, NEW YORK UNIVERSITY. Volume I, 1915.

THIS volume, edited by Dr. John William Draper, is composed of reprints of twenty-seven articles on various topics by certain physicians and surgeons connected with the New York University, together with an announcement regarding courses in research work in surgical pathological physiology that are offered in that University. A short "Foreword" is contributed by Dr. William J. Mayo, in which he remarks that the growing practice of republishing in one volume the results of investigations of a group of men studying different aspects of the same subject is most helpful; and, referring to this volume in particular, he says that the contents should be familiar to every surgeon, since its subject matter is representative not only of the surgery of to-day, but of to-morrow. Upon reading this volume we must say that Dr. Mayo has expressed our own sentiments most happily.

There are so many topics discussed that it is manifestly impossible to enumerate them here. Some papers detail studies upon the alimentary and neural canals; others discuss the Abderhalden reaction in its various aspects, particularly in its relation to surgical diagnosis; shock comes in for its share of attention; there are a number of papers on renal and ureteral conditions; and many others on topics too numerous to mention individually. The *ensemble* is the result of much hard and infinitely painstaking work by the authors; and we hope that the University authorities will continue to publish such volumes in the interest of the wider dissemination of accurate knowledge along these or similar lines.

THE CLINICS OF JOHN B. MURPHY, M.D., at Mercy Hospital, Chicago, Vol. V, No. 2, April, 1916. Octavo of 176 pages with 33 illustrations. Published bimonthly. Price per year, paper, $8; cloth, $12. Philadelphia and London: W. B. Saunders Company, 1916.

THE initial article in this number of the Clinics is a talk on the surgery of the tendons and tendon sheaths. Among the topics illustrated by clinical cases are: Wry neck; cervical rib, with a collective review on the surgery of cervical rib; hemorrhagic dural cyst; phlegmon of conus medullaris, with diagnostic discussion by Dr. Mix; musculospiral paralysis treated by tendon transference, and various other paralytic cases treated in this way or by tendon lengthening and fascial division; perforating ulcer of the heel; traumatic synovitis of the shoulder; and a number of others in addition to the usual crop of bone and joint cases. From the standpoint of the average subscriber we should say that this number deserves as strong commendation as the previous issue deserved criticism.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held April 24, 1916.

THE PRESIDENT, DR. FREDERIC E. SONDERN, IN THE CHAIR.

Resolutions upon the Death of Dr. Wisner R. Townsend.—Dr. ALEXANDER LAMBERT read these resolutions.

Resolutions upon the Death of Dr. Charles H. Richardson.—Dr. JOHN VAN DOREN YOUNG read these resolutions.

Delegates to the Medical Society of the State of New York.—Dr. J. MILTON MABBOTT was appointed to fill the vacancy caused by the death of Dr. Charles H. Richardson. Dr. Samuel J. Lopetsky was appointed to fill the vacancy caused by the resignation of Dr. Floyd M. Crandall.

The scientific session was devoted to a symposium on gastric and duodenal service as studied at the Mount Sinai Hospital.

Experimental Studies of Etiology of Gastric and Duodenal Ulcer.—Dr. HERBERT L. CELLER and Dr. WILLIAM THALHEIMER presented this communication, which was read by Dr. Thalheimer. Many attempts had been made to produce chronic ulcers experimentally in animals, but without success. Rosenow in a recent report stated that he had recovered streptococcus from 96 per cent. of excised gastric ulcers, and had produced acute and chronic ulcers in 60 per cent. of the animals injected intravenously with the streptococci. These streptococci were non-hemolytic and corresponded to the *Streptococcus viridans* or mitis type. As a result of these investigations Rosenow came to the conclusion that non-hemolytic streptococci were the cause of gastric ulcers in man, but that these organisms reached the stomach by a hematogenous route. They used the same technique as Rosenow, a description of which was furnished by him. Recently isolated cultures were used for animal inoculation as recommended by Rosenow. They examined eight ulcers removed at operation, and the consistency of the results obtained warranted this report. All of the ulcers were of the chronic indurated type. From six ulcers they recovered non-hemolytic streptococci—streptococci were seen in cultures from the seventh, but could not be isolated—and from the eighth no streptococci were recovered. Yeast was recovered from four ulcers. These resembled saccharomyces. They studied an additional specimen of peptic ulcer which occurred at a gastroenterostomy stoma of a case operated upon two years previously, in which a pyloric exclusion and gastroenterostomy were performed for duodenal ulcer. Streptococci were also recovered from this peptic ulcer. They did not find organisms in the depth of the ulcers, as reported by Rosenow, but only on the surface. Streptococci and yeast were the common findings, but other types occurred as well. As a result of their studies it was impossible to decide definitely whether or not the gastric lesions produced by the injection of streptococci were to be considered ulcers. The superficiality of the rabbit lesions following the injection by the intravenous route, as well as the entire absence of inflammatory reaction in the deeper gastric tissues, inclined them to believe that these defects were certainly not analogous to the chronic ulcer seen in the human stomach. The promptness of healing in the embolic lesions in the cats tended to strengthen this conclusion. It had been demonstrated by Bolton, Wilensky, Geist, and others that defects produced mechanically in the gastric mucosa and muscularis of cats healed in two to four weeks. In the defects produced in the rabbits by injection of streptococci into a branch of the gastric artery, these organisms were found in great numbers in the tissues about the lesions. By analogy it might be assumed, even in the absence of microscopic proof, that streptococci were also present at some time in the lesions in the cats. The embolic lesions in the stomach of the cats in their series healed spontaneously within approximately the same length of time as those mechanically produced. It was evident, therefore, that in these instances the injected streptococci failed to retard the process of healing. The constant presence of non-hemolytic streptococci in human gastric ulcers might be adduced as an argument in favor of the rôle played by this organism as the cause of the ulceration or its chronicity. If streptococci could be demonstrated in considerable numbers in the depth of human gastric ulcer this conception would gain a firmer basis. Gastrojejunal ulcer might readily be considered as due primarily to purely mechanical factors. Streptococci were recovered culturally from emulsified pieces of tissue. Although the histological picture was identical with that of the other ulcers in the series the most careful search failed to show the presence of streptococci on the surface of the lesion or in the tissues about it. One must consider the possibility that in this case the streptococci were directly deposited upon a preexisting mechanical defect and were not the essential causative factor in the formation of the ulcer. The nature of both the experimental gastric and cardiac lesions indicated that the streptococci recovered from the ulcers were of a low grade of pathogenicity. In addition to the streptococcus other organisms were invariably recovered from the inoculated tubes. No attempt was made to identify these strains culturally. The same types were usually identified microscopically in sections, proving that the isolated organisms other than streptococci were not accidental contaminations. Furthermore, these bacteria were quite as numerous in the sections as streptococci, and penetrated to the same depth in the ulcer. The types most frequently encountered were yeast and a thick Gram positive bacillus. Some of the isolated strains of yeast proved pathogenic for rabbits on intravenous inoculation. Their data were insufficient to warrant an expression of opinion as to the sigificance of these organisms. In conclusion they stated that it must be assumed that some cause was operative in certain cases of gastric ulcer and prevented the healing of defects in the gastric mucosa and was inoperable in others. Even though non-hemolytic streptococci were present practically in all gastric ulcers, they could not convince themselves that these organisms had been proven as yet to be the factor which either initiated the ulceration or prevented healing. Nevertheless, the constant presence of streptococci in this type of lesion was a suggestive fact, and further experiments to determine their significance were being undertaken.

Consideration of Causes of Recurrent Symptoms After Operation for Gastric and Duodenal Ulcer.—Dr. ABRAHAM O. WILENSKY read this paper. He said the surgical treatment of ulcer of the stomach or duodenum did not terminate with the completion of the healing of the abdominal wound and the discharge of the patient from the hospital. It should be followed by a long period of careful after-treatment directed toward the correction of those accompanying disturbances in the functions of the stomach which were always initiated by the ulcerative process. Such treatment was properly in the domain of the general practitioner from whom such patients were usually referred for operation, or in that of the expert medical man devoting himself to the care of these disorders of the stomach or duodenum. During this postoperative period symptoms frequently arose referable in a general way to the original seat of trouble, at times at variance with those complained of before operation, at other times mimicking those anteoperative symptoms in some of their aspects, and often again reproducing the original symptom complex. In order to point out the causes productive of these postoperative symptoms, they had made a careful study of all the patients operated upon for gastric and duodenal ulcer and had correlated the complaints of these patients with anatomic and pathologic facts made evident at secondary operations, and had attempted to show the physiological relationships between the resultant postoperative symptoms and the causative objective findings. When these patients were discharged from the hospital the subjective symptoms had been alleviated and the gnawing pain and distressing nausea and vomiting had disappeared; the patients then believed that a cure had been accomplished, and excesses were immediately committed, and enormous quantities of food taken. What happened then gave them, perhaps, the largest group of cases. The most common symptom was vomiting: if not corrected pain, pyrosis, and gaseous eructations appeared. Ulcer of the stomach or duodenum was almost always associated with changes in the quality and relative quantities of the ingredients of the gastric juice, and this disturbed condition of the normal secretory function gave rise to symptoms that appeared immediately or very shortly after operation. The great majority of these symptoms orginated in indiscretions in diet. The usual symptoms were pyrosis and belching. Secondary symptoms due to a reflex interference with the motility of the large intestine led commonly to various degrees of constipation and

in a few cases to diarrhea. There were some patients who began to complain even before their discharge, and the symptoms described were exactly the same as were present before the operation. Secondary operations might be done, and it would be impossible to find traces of any open ulcerations or of the scars of any healed ulcers, or in fact any other intraabdominal lesion amenable to surgical treatment. It might be assumed, therefore, that these patients had never had any lesion in the stomach and that the original operation had been unnecessary.

Cases were also found in which pain was experienced for a short time following operation, due to a want of accurate apposition in the suture line of the gastroenterostomy or remaining after the excision of the ulcer-bearing area. True peptic ulcerations appeared in the line of the stomach or a short distance therefrom in the jejunum in about 2 per cent. of those patients who had a recurrence of their symptoms, and the clinical picture was very characteristic. A reproduction of the original symptom complex occurred in a short time after the operation and the patient believed that the old ulcer had reappeared. Progression might be very rapid and perforation with its consequent peritonitis might quickly arise. Secondly, the symptoms continued much as before the operation. Most of the cases of gastrojejunal ulcer belonged to this group. Thirdly, the symptoms developed slowly and a tumor formed in the upper abdomen. Operation revealed a fairly large jejunal ulcer which had undergone subacute perforation and had become surrounded by a large mass of indurated and adherent intestine and omentum. Fourthly, such a tumor developed suppuration within it and the abscess ruptured into an adherent hollow viscus. In other patients the period of good health extended over a much longer period than was indicated in the previous groups, the symptoms beginning insidiously and increasing slowly. Vomiting soon appeared and became prominent and disturbances were found in the mechanics of the stomach. In some patients there seemed to be a natural predeliction toward the formation of postoperative intraabdominal adhesions. As regards the recurrence of the ulcerations or the formation of new ulcerations, one might say very little for they were as little enlightened in this respect as in the etiology of the original ulcer.

Limits of Operability in Carcinoma of the Stomach.—Dr. RICHARD LEWISOHN read this paper. He said that the question of surgical interference in cases of cancer of the stomach was still very much under discussion. Though this subject had been widely debated for over thirty years, opinions as to the advisability of surgical interference in these cases still differed very widely. On the one hand they found many of their colleagues who claimed that every case in which a diagnosis of cancer of the stomach had been established ought to be operated upon; on the other hand, they often heard the opinion expressed, and mainly from their medical confrères, that once the diagnosis of cancer of the stomach was established an operation would be useless, because at the very best such an operation might prolong life for a few months only. There could be no doubt that their present operative results were far from being perfect. Their operative statistics could be improved materially if these cases were turned over to the surgeon at a much earlier date than had been the custom before. The physician hesitated to subject his patient to an operation unless he had established the diagnosis beyond a doubt. This brought up the question: "What established the diagnosis of cancer?" It should be stated most emphatically that all the clinical findings varied very materially in the different cases, and if they waited until all their clinical data pointed absolutely toward cancer of the stomach, the time for the possibility of a permanent surgical cure of this disease had usually been passed. At Mount Sinai Hospital during the last three years, 134 cases of cancer of the stomach came under observation. A detailed investigation of the different clinical factors which led them to establish the diagnosis proved that in many of the cases only a small percentage of the so-called cardinal symptoms were present. Lactic acid, which was often considered as one of the cardinal symptoms, was absent in 30 per cent. of the cases, whereas free hydrochloric acid was present in about 40 per cent. Frequent and persistent vomiting was often found in pyloric tumors, whereas carcinomatous growths of the lesser curvature rarely caused vomiting. Many a case of gastric carcinoma had been treated medically for an unduly long time because of the erroneous argument that a diagnosis could not be established in the absence of vomiting. The absence of blood in the stools, blood in the vomitus, palpable mass, etc., did not by any means exclude the presence of gastric carcinoma. Youth did not exclude the presence of gastric carcinoma for 13 per cent. of their patients were under 40 years of age and one was only 25 years of age. Even the *x*-ray had failed them in some cases which were proven to be stomach cancers on the operating table. They had no diagnostic symptom which made the diagnosis an absolute certainty and, in order to give to the greatest number of patients the benefit of a possible radical cure, they had to risk an occasional unnecessary exploratory laparotomy. However, their experience had shown that such an exploration with a negative result was very rare. Even in cases which clinically gave the suspicion only of cancer of the stomach, the operative findings usually showed that the growth was much more extensive than they had assumed from their clinical studies of the case. What advice should they give to patients who came to them with large palpable tumors? Their experience caused them to believe that cases of large carcinomas of the stomach could be divided into four groups. (1) If a large tumor of the stomach was causing pyloric stenosis, the indication for operation was clear. If a radical operation was possible, such a tumor should be removed, otherwise a gastroenterostomy. (2) An attempt at operative interference ought to be made if the general cachexia was not too far advanced. Localized metastatic involvement was no contraindication; such glands could be easily removed with the tumor *en masse*. In a great many cases the patients with large tumors were very good operative risks. In the majority of the cases the removal of the tumor was technically very easy. (3) These were cases with large movable tumors and metastasis which made a radical cure impossible. A removal of the tumor would prolong the life of the patient and make his existence much more comfortable. (4) Fixed tumors of the stomach with extensive metastasis. These were really the only inoperable cases. The current idea that when a large tumor was palpable the case must surely be inoperable on account of extensive metastasis was certainly not in accordance with their observations. Among the 134 cases which were admitted in the last three years, 22 were considered as having inoperable tumors and the patients were sent home. In 28 cases only a palliative operation was possible, and in 51 cases nothing but an exploratory operation was performed. Resection of the tumor was possible in 33 cases. They did not consider that the size of the tumor alone was a contraindication if the general condition of the patient, metastasis in the liver or in the cul-de-sac and other considerations did not stamp the case as obviously inoperable. Although very many of these cases made an uneventful recovery, the number of radical cures was very small, between 5 and 10 per cent. Being aware, however, of the fact that operative interference was the only possible means of a cure and that without operation these patients had no chance of recovery, they should not be too conservative in their operative indications. For the present the knife of the surgeon offered the only possibility of a radical cure.

Recurrent Ulcer of the Stomach and Gastric Jejunal Ulcer.—Dr. ALBERT A. BERG described the method employed by him in doing a gastroenterostomy plus pyloric exclusion. He was very optimistic regarding the results recently obtained.

Dr. LEOPOLD O. STIEGLITZ said, that he wished that the internist who saw many cases of ulcer of the stomach or duodenum could share Dr. Berg's optimistic views as to the ultimate result of the operative treatment of this condition. The internist might be more ready and willing to submit their cases to the surgeon if the permanent results obtained were as satisfactory as those obtained by the surgeon in the treatment of appendicitis or gall stone disease; in the latter cases the internist could feel confident, that the surgeon would achieve an actual cure by the removal of the "causa peccans" of the patient's illness. But in operating for ulcer of the stomach the surgeon did not change the underlying morbid condition, that originally led to the formation of an ulcer—an ulcer was not a disease in itself, but rather a complication of a morbid gastric condition—and gastroenterostomy did not permanently affect this underlying morbid condition, nor change the factors that originally caused the ulcer to form. It was very much like treating an ulcer of the leg without paying any attention to the varicose veins that were the real cause of the ulcer formation. The cause of

failure in many of the operated cases might be ascertained by a careful study of the individual case. Thus in a case of ulcer of the pyloric region with total anacidity in which very profuse hemorrhages had led to operative interference a gastroenterostomy had been done with occlusion of the antrum. Within a week another profuse hemorrhage had occurred; some nine months later another one and two years thereafter another almost fatal hemorrhage. Now the *x*-ray had shown that in achyllia gastrica the pylorus was not tightly closed, and there was reason to assume that some of the peptic ulcers of the pyloric region were caused by the regurgitation of pancreatic secretion through the patent pylorus into the anacid stomach, where self-digestion took place. If that was the case it was easy to understand why in the case in question the hemorrhages had recurred, as there was nothing to interfere with the continued regurgitation of pancreatic secretion into the antrum of the stomach. He also reported another interesting case with enormous hyperacidity in which the operation had not given permanent relief. He stated, however, that the results achieved by medical treatment—as far as the question of permanent cure was concerned—were about as disheartening as those by surgical methods. They could not promise the patient that any medical or surgical methods would effect a permanent cure. But these cases certainly offered a splendid field for further study and investigation.

Dr. Seymour Basch said that the field of gastric ulcer was very broad and few had any conception of the problems attending the solution of the questions arising; all surgical and clinical investigations were of great value, but it was well to check both the surgeon and the internist. Only recently the experimental work of Rosenow had taken the world by storm. His investigations, however, could not be substantiated. The results obtained in experiments on animals were not the same as those obtained in the human being. In animals the incidences in their lives were vastly different from those in the human being. The first consideration must be paid to the public. How frequently did not the people state that in these cases of gastric or duodenal ulcer operation was the last resort. Again, frequently the internist was convinced that a patient should be operated upon, but yet the patient would put the time of operation off so long that the operation would fail to do him any good; then, too, the operation would jeopardize the life of the patient at this late period. Surgeons were often at fault because they lacked a unanimity of opinion as to the treatment. The internists were at sea because they were not able to interpret the findings and state what the end results might be. The patients lost confidence. Dr. Basch believed, however, that these cases could be better clarified if they were studied in a broad and proper way. It was better for the patient if he was in a hospital where he could receive the benefits of the laboratory, the *x*-ray, and better clinical observation. The worse cases were those who were without the hospitals. If they could adopt in private practice the methods employed in the hospital they would without doubt get better results. One of the best means for dividing the surgical from the medical cases was the *x*-ray. This would show the uncomplicated cases that would be better treated by the internist; it would also point out the cases in which certain complications had occurred and where medical means would not avail. With regard to some of the causes of recurrences in the late cases, they had not been as yet sufficiently studied out, but it was well known that certain concomitant conditions were often overlooked. Some frequently did not make a diagnosis of ulcer, and yet ulcer was present. One late cause was the gradual closing of the gastroenterostomy opening and another the making of an opening too high up. A frequent cause of failure was that the surgeon did not turn the patient over to the internist for treatment after operation. Again the internist was often very careless in the after-treatment. There were two points in the treatment that Dr. Basch wished to emphasize, the importance of rest and protection. If one gave us improper diet there could be no rest for the ulcerous area. In many cases of chronic ulcer wonderful results were obtained from the use of the duodenal tube, which gave both rest and protection to the area involved.

Dr. Edward A. Aronson said that the papers and the discussion they had listened to led them to the old battleground, the medical treatment *versus* the surgical treatment for the cure of gastric and duodenal ulcer. It was hardly fair to make a comparison for the following reasons: The internist could never be positive about his diagnosis because there was no *absolute* diagnostic sign of the presence of an ulcer. The surgeon sometimes erred also for an ulcer might be present or absent, and they could only accept his word as to its presence when he opened and inspected the stomach itself. The personal equation of the surgeon counted for much in that one surgeon would consider an induration another would pass by and regard the contrary. They based their estimate on surgical statistics, but this was wrong, because no two surgeons operated exactly alike. The economic conditions of their patients also played a big rôle. The bread-winner of the family wanted a quicker road to complete recovery, and they could expect this sooner from surgery than any medical means. This accounted in a way for the selection of cases for medical and surgical treatment. The former class included patients whose financial condition was so much better than the latter. Dr. Aronson said he had been in the fortunate position of being able to see a very large amount of postoperative material which was directed to his clinic at the Mount Sinai Hospital Dispensary from the surgical divisions of the hospital and to study the results of both medical and surgical treatment of ulcer. When the patient was returned to the physician uncured, that was, still complaining of symptoms referable to his stomach after surgical treatment, he believed it was his first duty to endeavor to determine whether any complication of the operation was present, whether the symptoms were due to indiscretions in both choice and quantity of food, whether they were purely nervous, or whether the original disease was still causing the symptoms. Consideration of the complications of the operation constituted a most important factor because the frequency of these complications resulting from surgical technique depended upon the experience of the surgeon. It was needless to state that unfortunately not every surgeon could perform a properly functionating gastroenterostomy, and it was also gratifying to say that as a result of improved technique many of the former frequent bad surgical results were rapidly disappearing. Retention of food or the presence of a large amount of gastric secretion in the stomach was an important factor in preventing the normal healing of an ulcer, and the object of gastroenterostomy was partly to facilitate the emptying of the stomach and to prevent any retention of food or undue increase in the normal intragastric pressure by excessive peristalsis. The majority of cases cured by gastroenterostomy were those in which there had never been any difficulty whatever in the emptying of the stomach. At the present time the late end results of surgical treatment, that was, gastroenterostomy plus pyloric exclusion for ulcer, were being studied, some of the patients having been operated upon almost three years ago. In the majority of those patients who complained of symptoms referable to the stomach, it had been found that they were due to a retention of either food or gastric secretion dependent upon lack of muscular tone, that was, a diminished peristole of the stomach. The latter was determined by a rather novel method in the hands of two investigators at the hospital who would shortly publish their results. There was but little doubt that this so-called atony had a direct bearing on the prolongation of the symptoms.

Dr. F. B. Turck said that the negative findings were of value not only in eliminating all but the essential factors in a problem, but especially in correcting a false conclusion which might otherwise become established. These experiments of Celler and Thalheimer indicated that ulcer was not produced by streptococci. They also showed that in no case of ulcer in man could streptococci be found in the deeper tissue. It was shown long since by Holman, Nauwerck, and others that any erosion or ulcer in the stomach would show bacterial forms on its surface, including, of course, the streptococcus; but such findings had no significance—no causal relationship to ulcer. Dr. Turck's experiments, published in 1906, showed that bacterial injections did not produce ulcers in animals. Only by the feeding of intestinal bacteria could peptic ulcer be reproduced just as it was found in the human stomach. As regards the surgery of ulcer, he personally considered perforation and cicatricial stenosis as the only indications. Senn, ten years ago, and Bland Sutton to-day gave weight of opinion against routine operation. This was in line with recent conclusion of Kuttner, Faulhaber, von Redwitz, Boyd, E. von Herezel

Pester, and Zweig. The reason of surgical failure was explained by the observations of Hamburger and Leach. Rational treatment would consider the whole ulcer status rather than merely the local lesion of ulcer itself and an outline of this therapy was to be published very shortly.

Dr. MARK I. KNAPP said he would confine his remarks only to the question of the etiology of ulcer. They had heard the analogy of gastric and duodenal ulcer to ulcer of the leg, as caused by varicose veins. This comparison was excellent. In the leg they had the bursting of a distended vessel, which resulted in an ulcer, because of the inability of the constantly irritated surface to heal. If then, they were to have in the stomach similar conditions, they could understand the formation of ulcers here. If they should have varicose veins in the stomach, they would have the first conditions necessary to ulcer formation. Had they such varicose veins in the stomach? Why, yes; varicose veins in the stomach were quite frequent. Did such dilated, varicose veins in the stomach ever rupture? Again, yes. He reminded them of the condition known as hemorrhagic erosions of the stomach. The hemorrhages did issue from the dilated and distended vessels, which burst open. Again, Dr. Thalheimer told them of yeast being found in the ulcers and also streptococci. If, now, such burst vessels were prevented from healing by the constant irritating presence of microorganisms and yeasts, they got the open, non-healing wound of ulcer. Dr. Thalheimer spoke of the presence of yeasts. He reminded them of his article on "Organacidia Gastrica," published in the MEDICAL RECORD, September 6, 1902. It was there he described for the first time organacidia gastrica, and made three subdivisions, one of which he named "zymosia gastrica," which meant yeast fermentation in the stomach. It was in this disease, where they found not plain yeast cells—these did no harm—but the growing, budding, sporulating yeasts and microorganisms, which were of grave consequence. It was the presence of these which kept the exposed, torn vessel from healing and developed the ulcer. And now the question was, how did they get the distention and thinning of the vessels? Here they had to think of the vessels as they ran through the muscularis. If there was a great spastic contraction of the muscularis, the return circulation would, for the time being, be impeded or, perhaps, stopped altogether. If such contraction again and again recurred, the result would, of necessity, be an attenuation and finally a rupturing of the distended vessel, the same as in hemorrhoids. Therefore, for the production of an ulcer they must have repeated spastic contractions of the muscularis with consequent distention and attenuation of the choked-off vessel, the final rupturing of such distended vessel, and, in addition thereto, there must be chronically present in the stomach irritating material, which irritated the wounded surface of the torn vessel and, not only, prevented it from healing, but caused the attendant inflammatory changes around the wounded vessel, the identity of which was finally effaced by the inflammatory exudate and infiltrate surrounding it. Therefore, prolonged irritation caused within the stomach, if continued for long time, the chronic spastic contractions of the muscularis which would ultimately lead to the developing of ulcer. The continued chronic irritation of the stomach proceeded from the pathological presence within the stomach of the volatile, acrid, irritating organic acids, mentioned and described by him in the article above mentioned. The presence of these acids must not be assumed, but proved by the tests which he had given and which were so easily and rapidly performed.

Stated Meeting, Held May 22, 1916.

THE PRESIDENT, DR. FREDERIC E. SONDERN, IN THE CHAIR.

Modern Methods in Municipal Milk Control.—Dr. CHARLES E. NORTH presented this communication, which was illustrated with lantern slides. He said there were four objects of municipal milk control which must be the aim of the public health officers in undertaking municipal control work and were as follows: (1) To insure the food value of milk as an article of food. This referred to those physical and chemical characteristics which identified it as milk, including standards for its chemical components, such as butter fat, total solids, solids not fat, and salts. (2) To insure so far as possible the safety of milk. This referred to the prevention of milk infections, and the prevention of the transmission of disease by milk. Specifically, it related to the bacteria of infectious diseases transmissible by milk, and to bacteria which could not be well recognized as specific, but which damaged the milk itself or by toxic products damaged the milk consumer, especially infants. (3) The promotion of decency as a characteristic of milk. The value of decency in food products deserved special consideration for its own sake, entirely apart from questions of safety. This subject related especially to the sanitary care which had been exercised to protect milk from contamination and pollutions so that it was clean and pure. (4) The provision for an abundant supply at the lowest price consistent with the characteristics above mentioned. The value of milk as a food made it desirable that it should be made available to all consumers at a moderate cost. Regulations which increased the cost so that it became a hardship to the consumer decreased the use of milk, and caused injury to persons who would benefit from its wider use. The methods used in the past in municipal milk control were chemical analysis, dairy inspection, veterinary inspection of cattle and tuberculin testing, medical inspection of employees, certified milk, and bacterial testing. The modern methods of milk control were considered under the following headings:

1. *Grades and Standards for Milk.*—The purpose of grading was to attach proper labels to milks of different sanitary character. It was recognized that there were an unlimited number of degrees of excellence, from the highest to the lowest. For practical purposes, in large cities arbitrary lines could be drawn between three degrees of excellence. The highest grade of milk, carrying a "Grade A" label, should be milk satisfactorily clean, which was entirely safe, and which could be sold at a reasonable price, although such price must be necessarily higher than the price of any other grade. The primary object of this grade should be to place before the public a milk satisfactory for infant feeding. The second grade milk should correspond to the bulk of the market milk in sanitary character, and be sold at the regular market price, and while not so clean, yet entirely safe, and suitable for drinking purposes, especially by persons who were not so sensitive to the requirements of decency in milk which was to be used for drinking purposes. The third grade milk should be milk unfit for drinking purposes, but which still had some value for manufacturing purposes. In small cities two grades might be sufficient: "A" and "B." The lines of division should not be drawn until a careful survey of local conditions had been made, and the degrees of excellence on which these lines were based would necessarily differ in different communities.

2. *Pasteurization and the Place It Should Occupy.*—Pasteurization had come to occupy a place of first importance in furnishing a guarantee of safety to milk. No other measure yet discovered was able to give a life insurance to milk, or to protect milk consumers against infectious bacteria. The alleged objections to pasteurization as causing changes in the food value of milk were not substantiated by extensive medical observation. While there was some evidence that the feeding of pasteurized milk in infants might, in some cases, tend toward the development of rickets or scurvy, yet the feeding of orange juice so easily offset any such tendency that this objection could not be permitted to offset the enormous advantages to be gained by pasteurization. The infectious diseases caused by raw milk, even of the best character, justified the pasteurization of all milk, including such raw milk as certified. Pasteurization could be easily controlled by public health authorities by the use of recording instruments and bacterial testing.

3. *Tuberculin Testing, and the Place It Should Occupy.*—Tuberculin testing of dairy cows had been emphasized unduly by many municipalities as a measure of primary importance in safeguarding municipal milk supplies. In the first place, tuberculin testing was protection only against bovine tuberculosis, and was not a protection against any other infectious disease transmissible by milk. In the next place, it was not a complete protection against bovine tuberculosis even in the hands of the best dairymen and veterinarians. Experience had repeatedly shown the presence of tuberculosis in dairy herds and in certified dairies which were under the supervision of medical milk commissions. Tuberculin testing had a place, but only a small place, in municipal milk control. The pasteurization of

milk entirely destroyed the tubercle bacilli, and the adoption of pasteurization made tuberculin testing unnecessary as a protection against bovine tuberculosis. Such testing then became primarily an economic measure, which it was desirable to use for the protection of dairy herds and of the dairy industry. In most large cities at best but a small portion of the milk supply could be obtained from tuberculin tested cows. The complete control of bovine tuberculosis by this test in most dairy districts would mean the loss of from 30 per cent. to 50 per cent. of dairy cows, a milk famine, and an enormous increase in the price of milk, without corresponding benefits to the milk consumer.

4. *Vetcrinary Inspection of Cattle.*—Dairy cattle should be free from obvious disease. Common decency demanded this. Cattle diseases that could be detected by the physical examination of a competent veterinarian should be eliminated. To accomplish this it was necessary to establish regulations requiring periodic physical examination of dairy cows.

5. *Medical Inspection of Dairy Employees.*—Dairy employees should also be free from obvious disease. Regular medical examinations to determine this involved an expense hardly justified where the milk was to be pasteurized. The only safeguard in this matter upon which the public could depend was the reporting of cases of infectious diseases by the dairymen. This was not worth much, but was all that it seemed feasible to request at present.

6. *Bacterial and Chemical Testing, and Its Function.*—The milk testing laboratory must necessarily make a sufficient number of chemical tests to determine whether milk was being adulterated, or watered, or skimmed, or altered in any way dishonestly. Prosecutions based on these tests were almost universally practiced by municipal, state, and federal authorities, and should continue as a fundamental part of the municipal milk control. The bacteriological laboratory had a much larger function to perform. The close parallel between the numbers of bacteria in milk and its sanitary character made the bacterial test the surest and most valuable means of detecting faults in milk sanitation. When milk was clean and fresh the numbers of bacteria were certain to be very low. When it was dirty or stale, the numbers would be very high. It was always certain that milk containing large numbers of bacteria was either dirty or stale, or both. In the grading of milk the lines drawn between the different grades should be based on difference in sanitary character. This meant differences in contamination with dirt, and in staleness due either to age or lack of refrigeration. Consequently the most important element in milk grading should be the bacterial standard for each grade. In well conducted laboratories the variations between consecutive tests of the same milk was so small that only a few such tests were necessary to give a correct index of the sanitary character of the milk. Five consecutive tests showed plainly the sanitary grade in which a milk belonged. The laboratory testing of milk was no longer a matter of mystery or great expense, but could be put on an efficiency and business basis which made possible a large volume of testing at comparatively nominal expense to municipalities. Laboratories capable of testing 100 samples of milk daily could be installed for $200. Laboratory workers capable of plating and counting from 50 to 100 samples daily could be secured in many places from $10 to $12 a week salary. Thus every municipality could have its own bacteriological laboratory, and even small towns and villages could be possessed of these facilities. Milk dealers, even those having comparatively small businesses, could afford to conduct regular laboratory tests for bacteria. Another new and most important function of the bacterial laboratory was that it should act as a guide to dairy inspection. By proper distribution of bacterial tests over the supplies of the milk dealers distributing milk in a municipality, the health department could soon ascertain what dealers were bringing clean and fresh milk, and what dealers were bringing dirty and stale milk into the city. The bacteriological laboratory also quickly furnished information as to the efficiency of pasteurization. The tabulation of these reports concerning the character of raw milk and pasteurized milk, for the first time in the history of milk control, laid a correct foundation for intelligent dairy inspection. The assembling of bacterial tests on the desk of an officer in control of dairy milk supply made it possible for him to direct the force of dairy inspectors toward those places which were most in need of such inspection.

7. *Dairy Inspection, and the Place It Should Occupy.*—Dairy inspection had for years been made prominent as a means of milk control. There had been a tendency toward the development of dairy inspection as such in many municipalities to an extent that had overbalanced other methods of milk control, and actually interfered with progress in the right direction. In some municipalities the money and time devoted to the work had not been reflected in a corresponding involvement in the character of the milk supply. Dairy inspection without bacterial testing was aimless. Without the bacterial test, the dairy inspector went to his work blindfolded. Without a knowledge of the results of the bacterial tests of milk from a given dairy district the dairy inspector devoted his time, in many cases, to dairies which needed no inspection and, in many instances, devoted too little time to dairies which were the real sources of polluted milk. The product itself was the object of primary importance to the producer, the consumer, and the health officer. Dairy inspection alone did not lay its emphasis on the product, but on the environment of the product. The place to lay the emphasis in municipal milk control was on the product itself. The first step toward this was the grading of the milk and the establishment of milk standards. This grading should be based primarily on the sanitary character of the product, and not on the dairy score or the inspection of the dairy. The next step in transforming the product was the establishment of a system of laboratory testing of milk for bacteria. Such tests could be made in very large volume at very small cost. By voluminous bacterial testing of this sort the health officer could be abundantly supplied with constant information as to the sanitary character of all sources of the municipal milk supply. By these same tests he could also keep constantly informed regarding the efficiency of pasteurization. Armed with this information, properly tabulated, and in the hands of a central office, the force of dairy inspectors could then be controlled so that its activities, instead of being aimless, vacillating, or uncertain, became concentrated on worst portions of the milk supply as indicated by the laboratory test. The force of milk and dairy inspectors became virtually a flying squadron, directed toward the places where they would do the most good. This meant most intimate coordination between the bacterial and chemical laboratory work and dairy inspection.

Prof. W. H. Conn of Wesleyan University said that the first work on bacteria had been done in his laboratory twenty-nine years ago and since then a great many changes had taken place. The dairy industry had been revolutionized and many early ideas regarding the bacteria had been changed, as well as modified, until now many of their early beliefs of the early days were gone. During that time the significance of bacteria had steadily grown; the bacterial content of the milk had gradually impressed itself upon us until to-day the greater significance of the organisms was greater than ever before. Many attempts had been made to control the milk problem. He said he was sure that the medical profession to-day more fully realize the dangers that are associated with milk than ever before. A great many attempts had been made to get control of the milk industry. Dairy inspection alone did not insure the safety of the product. In 1889 he first made the suggestion to the dairymen in neighboring cities that the dairy inspection would some day be adopted by the municipality, and he was looked at with great amazement. Professor Conn said he wished to say a few words concerning the attempts that had been made to control the problem. Of all these the best had been the system of graded milk and a change that is developing with great rapidity at the present time. New York City was its home; it started in this city, and the influence it exerted extended elsewhere. This graded milk furnished a safe milk for the masses, and this was the key to the whole thing. This grading of the milk unites the producer, the dealer, and the consumer in one common interest. Emphasis was laid upon the four following points in connection with the bacterial standard of milk: (1) Clean, fresh milk from healthy cows would always give a low bacterial count. (2) The high bacterial count would always come from either dirty milk, stale milk, warm milk, or milk from diseased cows. (3) It was perfectly possibly to furnish even New York with a milk of low bacterial count. (4) Taking all things together the bacterial count of milk gives more information concerning the nature of the milk or its wholesomeness than any one fact. The main point he wished to emphasize was that the grad-

ing of the milk supply which was spreading from New York to other cities should be by new administrative methods. The administration of the milk industry in our communities had developed in the past years under different conditions. In earlier years they had aimed at finding men who were delinquent in producing and selling milk illegally, so that they might be taken to court and possibly fined. It was hoped that from such stimulus the dealers would produce a product of milk that was of a proper grade. Now the attempt should be to determine the grade of a dealer's whole supply. New administrative measures were now needed. The grading of milk involved bacteria testing, dairy inspection, and especially the coordination of the two in order to prevent conflicts, to prevent waste of effort, and to pick out delinquent dairies and diseased cows.

Dr. Haven Emerson, Commissioner of Health, New York City, called attention to the policy of the Department of Health in considering matters pertaining to the milk supply and the work that had been done and was being done in connection with the various milk commissions in educating the people with respect to *clean* milk. The New York County Medical Milk Commission, the New York Milk Committee, and the National Commission on Milk Standards had been impressed with the importance not only of local municipal but State control of the milk supply. There should be a closer cooperation between the local and rural health officers of different localities responsible for the care of the communities, so that it would not be necessary to send inspectors from cities into the country to inspect the conditions of milk production. Dr. Emerson referred to the outbreak of typhoid fever in Bay Ridge, where there occurred about one hundred cases infected by milk contaminated by a typhoid carrier who had also been responsible for a number of cases that had recently occurred in a village in New Jersey. This carrier infected the water supply of the dairy. The value of country milk inspections lay in its educational effect. The inspectors should be graded according to the educational work they do. It was interesting to note that the attention of the consumer was being directed to other factors in connection with the milk supply beside the "cream line." The people were now buying milk according to the grade and not according to the "cream line." They recognized safety as of greater importance. The suggestion had been made that the city should not use certified milk or other raw milks, but he believed, contrary to what had been stated, that there would always be a proper demand for a high grade raw milk. It should be possible always to produce raw milk that was safe enough to be marketable.

Dr. William H. Park said that he believed that probably Dr. North was better known in the work on the milk problem than any one else and had done much to simplify the problems confronting them; for instance, he had emphasized over and over again that it was not necessary to have certain kinds of floors in the barns. If the milk was clean and had been pasteurized it would be all that was necessary for the ordinary milk supply. With what had been said regarding raw milk he said he could not agree. It should be remembered that the barns of to-day were supervised by men of intelligence; they were also owned by them. The bacterial count was purely quantitative and not qualitative. With regard to the safety of certified milk, it was impossible for them to say that somebody would not make a mistake. None of them, however, had been able to trace any disease resulting from the use of certified milk since 1902. Therefore, he thought it best to agree with Dr. Emerson that certified milk was a reasonably safe supply. He did not think it was quite fair for anyone to state that the New York City and the New York State and National Committees were responsible for the introduction of the graded milk. Dr. North had a great deal to do with the forming of the committee. The results of the work which had spread throughout the country were of great value. In the City of New York itself most of the good that resulted must have the credit given to Dr. Lederle and Dr. Biggs.

Dr. Linsly R. Williams said that although the present bacteriological examination of milk was eminently desirable, yet it was not feasible except in the larger cities, that pasteurization was of the greatest importance and that in the rural sections certified milk did not always mean that it was produced under ideal conditions. Dr. Williams urged physicians who were sending patients to rural New York for the summer or who, themselves, practiced in other parts of the State, to write to the State Health Department any complaint they might have of any local milk supply in New York State.

Some Recent War Experiences in the Hospitals of France.—Dr. Clarence A. McWilliams told of his experiences in France, where he was sent by the French Hospital to take charge. His talk was illustrated with terior of the hospitals, the trenches, the system of transporting the wounded, the wounded men, etc. lantern slides showing both the interior as well as ex-

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Ohio State Board of Medical Examiners.

June 6, 7, 8, *and* 9, 1916.

ANATOMY.

1. Name the subdivisions of the abdominal cavity.
2. Give a description of the knee joint.
3. Name the carpal bones.
4. Describe the prostate gland.
5. What is the length of the intestine and its divisions?

PHYSIOLOGY.

1. Describe the functions of visceral muscle.
2. What is the nature of the nerve impulse? Discuss nerve fatigue.
3. What are the advantages of a mixed diet? How does a purely protein diet affect metabolism?
4. What is the mode of secretion and discharge of the bile?
5. Give histology of blood plates.
6. Discuss intravascular coagulation. What pathological conditions of the vessels favor its development?
7. Locate the cardio-accelerator center. How is the heart rate affected through the vagus nerve?
8. Describe Cheyne-Stokes respiration. With what pathological states is it usually associated?
9. Describe effects of removal of parathyroid tissue.
10. What is the origin, distribution, and function of the third nerve?

CHEMISTRY.

1. Give the chemical formula for mercurous chloride, mercuric chloride, and mercurous nitrate. Give one characteristic of each.
2. State the difference between a physiological and chemical antidote for poison, and give an example of each.
3. What is organic chemistry? State the general properties of organic compounds.
4. Differentiate between fermentation and putrefaction.
5. What is methyl alcohol? Give formula, properties, and uses.

MATERIA MEDICA AND THERAPEUTICS.

1. Name the three principal serums. Give mode of administration and indication for use of each.
2. Name the different preparations of digitalis and aconite. Give dose and cumulative action of each.
3. Cocaine hydrochloride—its physiological action and principal uses. Give symptoms and treatment of an habitué.
4. For what purposes are diuretics employed. Name the principal ones. How are they usually classified?
5. Give the physiological action, use, and dose of salicylate of sodium.
6. Potassium salts—name the principal ones and give dose and use of each.
7. Name three external antiseptic remedies. Give indications, and state how each may be used.
8. Nux vomica—its therapeutic uses, important preparations—dose of each.
9. Give the indications for internal use of corrosive sublimate; state dose.
10. Give the therapeutic uses and state the dose of opium and its alkaloids.

DIAGNOSIS.

1. Give symptomatology of incipient pulmonary tuberculosis.
2. Give etiology and physical signs of myocarditis.
3. Describe difference in symptomatology of acute dilatation of heart and hypertrophy of heart.
4. How can the functional competency of each kidney be demonstrated?

5. Give differential diagnosis: ulcer of stomach, ulcer of duodenum, and cholecystitis.
6. Give early signs of hyperthyroidism.
7. Differentiate enlarged gall bladder and ptosed right kidney.
8. Describe physical signs of effusion in acute pleuritis.
9. What is the most important sign of leukemia?
10. What are the early signs of acute poliomyelitis?

PATHOLOGY.

1. What is the blood picture in myelogenous leukemia; give source of abnormal cells found.
2. What is a hemorrhagic infarct; what would be the course of such a condition—for example, in the kidney?
3. Describe tubercle formation, and the various pathological results in pulmonary tuberculosis.
4. Give method of preparing a vaccine for furunculosis.
5. Describe your precautions in treating a case of diphtheria: (*a*) for the physician; (*b*) for the patient's family; (*c*) for the general community.

ANSWERS.

ANATOMY.

1. The abdominal cavity is divided into the abdomen proper and the pelvis.
2. The *knee joint* is a ginglymus, and is formed by the condyles of the femur, the head of the tibia, and the patella. "The *external ligaments*: the *anterior* or *ligamentum patellæ* is the continuation of the tendon of the triceps extensor. Above it occupies the apex and rough marking on the lower and posterior surface of the patella; below it is attached to the lower part of the tubercle of the tibia. There is a bursa between the upper part of the tubercle and the ligament. The *posterior ligament* (*ligamentum posticum Winslowii*), broad and thin, covers the back of the joint. It consists of a central and two lateral parts. The lateral parts spring above from the femur above the condyles and are attached below to the head of the tibia. The central part is derived from an expansion of the semi-membranosus tendon, and passes from the inner tuberosity of the tibia to the inner side of the upper part of the outer condyle of the femur. The *internal lateral ligament*, broad and flat, is attached above to the inner condyle of the femur; below, to the margin of the inner tuberosity, to the internal fibrocartilage, and to the inner surface of the shaft of the tibia for 1½ inches. The *long external lateral ligament*, a rounded cord, is attached above to the external condyle of the femur, and below to the external part of the head of the fibula, dividing the biceps tendon into two parts, a bursa intervening. The *short external lateral ligament*, very indistinct, lies parallel and behind the preceding, attached above to the outer condyle of the femur, and below to the styloid process of the fibula. The *capsular ligament*, thin, fills up the intervals between the special ligaments; it is attached to the margins of the articular surfaces of the bones, and blends with the fascia lata of the thigh: above it receives expansions from the vasti (*lateral patellar* ligaments).

"The *Internal Ligaments*: The *anterior* or *external crucial ligament* is attached to the depression in front of the spine of the tibia and to the external semilunar fibrocartilage; it passes upwards, backwards, and outwards to the posterior part of the inner side of the external condyle of the femur. The *posterior* or *internal crucial ligament* is attached to a depression behind the spine of the tibia, to the popliteal notch, and the posterior border of external semilunar fibrocartilage, this latter slip being sometimes called the *ligament of Wrisberg;* it passes upwards, forwards, and inwards, the posterior fibers attached by side of oblique curve of inner condyle, the anterior ones to the fore part of intercondylar fossa and to the anterior part of the outer surface of the inner condyle. The *semilunar cartilages* are thicker at the circumferences than at the central margins and serve to deepen the cavities for the head of the femur. The *internal semilunar cartilage* is oval in shape, the anteroposterior diameter being the longer. Its anterior extremity is attached to the tibia in front of the anterior crucial ligament, and the posterior extremity in front of the posterior crucial ligament. The *external semilunar cartilage* is nearly circular; its anterior extremity is attached to the tibia in front of the spine, the posterior extremity to the back of the spine." (*Aids to Anatomy.*)

3. The carpal bones, from radial to ulnar side, are (in the first row) scaphoid, semilunar, cuneiform, and pisiform; (in the second row) trapezium, trapezoid, os magnum, and unciform.
4. The prostate gland is about the size and shape of a horse-chestnut, and surrounds the neck of the bladder and first part of the urethra in the male. It is surrounded by a dense capsule, and consists of three lobes (two lateral and one middle); it is pierced by the ejaculatory ducts and by the urethra. Its base is attached to the base of the bladder, and its apex is in relation with the posterior layer of the triangular ligament and the compressor urethræ muscle. The posterior surface is in relation with the rectum and is about an inch and a half from the anus.
5. The *small intestine* is about twenty-one feet in length, the *duodenum* being about ten inches, the *jèjunum* about eight feet, and the *ileum* about twelve feet. The *large intestine* is about five or six feet in length, the *cecum* being about two and a half inches, the *ascending colon* about five inches, the *transverse colon* about twenty inches, the *descending colon* about eight and a half inches, the *sigmoid colon* about seventeen inches, the *rectum* about five inches, and the *anal canal* about one and a half inches. All these measurements are liable to variation, particularly those of the large intestine.

PHYSIOLOGY

1. *The function of visceral muscle.* "In a general way is may be said that the visceral muscle determines and regulates the passage through the viscus or organ of the material contained within it. The food in the stomach and intestines is subjected to a churning process by the muscles, in consequence of which the digestive fluids are more thoroughly incorporated and their characteristic action increased. At the same time the food is carried through the canal, the absorption of the nutritive material promoted, and the indigestible residue removed from the body. The blood is delivered in larger or smaller volumes according to the needs of the tissues through a relaxation or contraction of the muscle fibers of the blood-vessels. The urine is forced through the ureters and from the bladder by the contraction of their respective muscles." (Brubaker's *Textbook of Physiology.*) During labor the uterus expels the fetus, followed by the placenta and membranes.
2. *The nature of the nerve impulse.* "As to the nature of the nerve impulse but little is known. It has been supposed to partake of the nature of a molecular disturbance, a combination of physical and chemical processes attended by the liberation of energy, which propagates itself from molecule to molecule. The passage of the nerve impulse is accompanied by changes of electric tension, the extent of which is an indication of the intensity of the molecular disturbance. Judging from the deflections of the galvanometer needle it is probable that when the nerve impulse makes its appearance at any given point it is at first feeble, but soon reaches a maximum development, after which it speedily declines and disappears. It may, therefore, be graphically represented as a wave-like movement with a definite length and time duration. Under strictly physiological conditions the nerve impulse passes in one direction only; in efferent nerves from the center to the periphery, in afferent nerves from the periphery to the center. Experimentally, however, it can be demonstrated that when a nerve impulse is aroused in the course of a nerve by an adequate stimulus it travels equally well in both directions from the point of stimulation. When once started, the impulse is confined to the single fiber and does not diffuse itself to the fibers adjacent to it in the same nerve trunk." (Brubaker's *Textbook of Physiology.*)

Nerve Fatigue. "Inasmuch as nerves are parts of living cells, the seat of nutritive changes, it might be supposed that the passage of nerve impulses would be attended by the disruption of energy-holding compounds, the production of waste-products, the liberation of heat, and in time by the phenomena of fatigue. Though it is probable that changes of this character occur, yet no reliable experimental data have been obtained which afford a clue as to the nature or extent of any such changes. Stimulation of motor nerves with the induced electric current for hours appears to be without influence either on the intensity of the nerve impulse or the rate of its conduction." (Brubaker's *Textbook of Physiology.*)

3. *Mixed Diet.* "The chemical composition of the tissues, taken in connection with their metabolism during starvation, implies that no one article of food is

sufficient for tissue repair and heat production; but that all classes of food—in other words, a mixed diet—are essential to the maintenance of a normal nutrition. Experimental investigation has also conclusively established this fact. Moreover, the amounts of nitrogen and carbon eliminated daily, and the ratio existing between them, indicate the amounts of proteid, fat, and carbohydrate which are required to cover the loss." (Brubaker's *Textbook of Physiology.*)

Metabolism on a purely protein diet. "Notwithstanding the chemical composition of the proteins and the possibility of their giving rise to both fat and carbohydrate during their metabolism, it has been found extremely difficult to maintain the normal nutrition for any length of time on a pure proteid or fat-free diet. This, however, has been accomplished with dogs. It was found, however, that, in order to maintain the equilibrium, it was necessary to increase the proteins from two to three times the usual amount. Thus a dog weighing 30 to 35 kilograms required from 1500 to 1800 grams of flesh daily in order to get the requisite amount of carbon to prevent consumption of its own adipose tissue. Under similar circumstances, a human being weighing 70 kilograms would require more than 2000 grams of lean beef—an amount which, from the nature of the digestive apparatus, it would be practically impossible to digest and assimilate for any length of time. Even the slight habitual excess beyond the amount normally required is imperfectly assimilated and gives rise to the production of nitrogen-holding compounds which, on account of the difficulty with which they are eliminated by the kidneys, accumulate within the body and develop the gouty diathesis, with all its protean manifestations." (Brubaker's *Textbook of Physiology.*)

4. *Mode of secretion and discharge of bile.* "Although the liver presents some physiological peculiarities there is no reason to believe that the conditions of secretion therein are different from those in any other secretory organ, or that any other structure than the cell is engaged in this process. As shown by chemical analysis, the bile consists of compounds, some of which, like the bile salts, are formed in the liver cells, out of material furnished by the blood by a true act of secretion, while others, such as cholesterin and lecithin, principles of waste, are merely excreted from the blood to be finally eliminated from the body. The bile is thus a compound of both secretory and excretory principles. The flow of bile from the liver is continuous, but subject to considerable variation during the twenty-four hours. The introduction of food into the stomach at once causes a slight increase in the flow, but it is not until about two hours later that the amount discharged reaches its maximum. After this period it gradually decreases up to the eighth hour, but never entirely ceases. During the intervals of digestion, though a small quantity passes into the intestine, the main portion is diverted into the gall bladder, because of the closure of the common bile duct by the sphincter muscle near its termination, where it is retained until required for digestive purposes. When acidulated food passes over the surface of the duodenum, there is an increase in the secretion, or at least the discharge of bile, and as this takes place after the nerves distributed to the liver are divided, the assumption is that an agent, possibly secretin, is developed in the duodenal mucous membrane, which, absorbed into the blood, is ultimately distributed to the liver cells and by which they are excited to activity. At the same time there is excited, through reflex action, a contraction of the muscle walls of the gall bladder and ducts, a relaxation of the sphincter, and a gush of bile into the intestine, the discharge continuing intermittently until digestion ceases and the intestine is emptied of its contents." (Brubaker's *Textbook of Physiology.*)

5. The blood platelets are small granular or homogeneous discs, about 1.5 to 3.5 μ in diameter. The edges are rounded and well defined; they have no nucleus; they have been estimated at about 250,000 to 300,000 to the cubic millimeter of blood.

6. *Intravascular coagulation.* "So long as the relations of the blood and the vascular apparatus remain physiological, no coagulation occurs in the vessels. The reasons assigned for this are: (1) the absence of thrombo-kinase in sufficient amounts; (2) the presence of an antithrombin. On either assumption the reaction between prothrombin and calcium with the formation of thrombin does not take place. If the vessels are injured as they are when ligated or torn or in any way impaired, coagulation promptly takes place with the subsequent occlusion of the vessel. As to whether the injured tissues or the blood cells now generate an agent, thrombo-kinase, which activates the prothrombin and calcium, or whether they generate an agent thromboplastin, which neutralizes an antithrombin, is a subject of discussion." (Brubaker's *Textbook of Physiology.*)

7. *The cardio-accelerator center* is in the medulla. The vagus nerve is the inhibitory nerve of the heart; it slows the heart. Section of one vagus produces slight acceleration of the heart. A more marked effect occurs when both vagi are divided. The inhibitory action of the vagus is continuous.

8. *Cheyne-Stokes respiration* "is a condition in which the respirations gradually increase in volume and rapidity until they reach a climax, when they gradually subside, and finally cease for from ten to forty seconds, when the same cycle begins again. It may occur in tuberculous meningitis, cerebral hemorrhages, embolism, thrombosis, aneurysm of basilar artery, uremia, heart disease, etc." (Hughes' *Practice of Medicine.*)

9. *Removal of the parathyroids* is followed by twitching and spasms of the voluntary muscles, paralysis of the legs, increased frequency of respiration, and death.

10. The *third cranial nerve* (motor oculi) arises from the inner side of the crus cerebri, in front of the pons, and from the floor of the aqueduct of Sylvius. It enters the cavernous sinus and then passes forward to enter the orbit through the sphenoidal fissure. While in the sphenoidal fissure it divides into two branches. It is the motor nerve for the following five muscles of the eyeball, and is distributed to these muscles: the superior rectus, levator palpebræ superioris, internal rectus, inferior rectus, and inferior oblique muscles.

CHEMISTRY

1. *Mercurous chloride*, Hg_2Cl_2, insoluble in water.
Mercuric chloride, $HgCl_2$, soluble in water.
Mercurous nitrate, $Hg_2(NO_3)_2$, is efflorescent.

2. *Physiological antidotes* act as such by combating one or more of the physiological actions of the poison, such as opium for belladonna.
Chemical antidotes act as such by uniting chemically with the poison and thus converting it into a harmless or insoluble compound, such as magnesium sulphate for lead poisoning.

3. *Organic chemistry* is the chemistry of the carbon compounds.
General properties of organic compounds: They may be solids, liquids, or gases; if solid, may be crystalline or amorphous; they may be volatile or non-volatile, and they are very liable to undergo change when acted upon by heat or reagents. The more complex they are, the more readily they undergo change.

4. *Fermentation* is a form of decomposition of organic matter containing only carbon, hydrogen, and oxygen.
Putrefaction is a form of decomposition of organic matter which contains nitrogen in addition to carbon, hydrogen, and oxygen.

5. *Methyl alcohol* is the hydroxyl of methyl, CH_3OH. It is a colorless liquid having an ethereal and alcoholic odor and a sharp, burning taste. It burns with a pale flame, giving less heat than that of ethyl alcohol. It mixes readily with water, alcohol and ether, and is a solvent for sulphur, phosphorus, potash, soda, and resinous substances.

MATERIA MEDICA AND THERAPEUTICS

1. *Antidiphtheritic serum* should be given to patients suffering from diphtheria, or even suspected to be suffering from that disease. It is given subcutaneously.
Antimeningococcic serum is injected into the spinal canal after the withdrawal of about 30 cc. of cerebrospinal fluid. It is administered to patients suffering from cerebrospinal meningitis.
Antistreptococcic serum is given in various diseases due to streptococcus infection (erysipelas, puerperal fever, septicemia, ulcerative endocarditis). It is given subcutaneously.

2. DIGITALIS. Fluidextract, ℥j; extract, gr. i-v; infusion, ℥ij; tincture, ℥xv.
Symptoms of cumulative effect of digitalis: Weak, dicrotic pulse, perspiration, nausea, vomiting, lowered reflexes, lowered body temperature, vertigo, muscular tremors, lassitude, delirium, stupor.
ACONITE. Fluidextract, ℥j; tincture, ℥x.
Symptoms of aconite poisoning usually manifest themselves within a few minutes; sometimes are delayed for an hour. There is numbness and tingling,

first of the mouth and fauces, later becoming general. There is a sense of dryness and of constriction in the throat. Persistent vomiting usually occurs, but is absent in some cases. There is diminished sensibility, with numbness, great muscular feebleness, giddiness, loss of speech, irregularity and failure of the heart's action. Death may result from shock if a large dose of the alkaloid be taken, but more usually it is by syncope.

3. Cocaine hydrochloride. *Physiological action:* Local anesthetic (externally); internally it is a muscular, cerebral, circulatory, and respiratory stimulant, also a mydriatic. Its *principal uses* are: As a local anesthetic; also in paralysis agitans, chorea, and alcoholic tremors.

The chief symptoms of an habitué, are:—"Emotional excitement, physical unrest, mental impairment, moral turpitude, hallucinations, mild epileptiform attacks, dilatation of the pupils, a rapid and feeble pulse, severe gastric disturbance, wasting and anemia. *Treatment*: The drug should be withdrawn rapidly but not suddenly. Treatment in a sanatorium is always advisable. Stimulants like strychnine are often useful. Hygienic and dietetic measures calculated to improve general nutrition are indicated." (Stevens' *Materia Medica.*)

4. *Diuretics are used:* To dilute the urine, to increase the flow of the urine, to remove liquids from the body (as in dropsy), to remove toxic substances from the body, and to stimulate atonic kidneys.

Diuretics are classified, as (1) Those that act as such by increasing the arterial pressure, digitalis, squills, and strophanthus are examples; (2) those that act by dilating the renal vessels, such as caffeine; (3) those that act as stimulants to the renal epithelium, such as caffeine, theobromine, scoparius, calomel; and (4) various salines which act by increasing the water in the blood, such as several of the salts of lithium and of potassium.

5. Sodium Salicylate. *Dose*, 15 grains. *Physiological action:*—Antiseptic; irritant; strongly cholagogue; antipyretic; diaphoretic; diuretic (markedly increasing the excretion of uric acid). In exceptional instances skin eruptions are caused, and in some individuals a train of symptoms analogous to those of cinchonism, and designated as *salicylism*, results from the use of salicylic preparations.

Uses:—Externally, as antiseptic and stimulating applications and for the checking of abnormal perspiration; also in parasitic and other skin diseases. Internally, rheumatic fever (in which it seems to act as a specific); gout; migraine; sciatica; diabetes; cholelithiasis. (Wilcox's *Materia Medica.*)

6. *Potassium salts:* Carbonate, gr. xv; bicarbonate, gr. xxx; acetate, gr. xxx; citrate, gr. xv; sulphate, gr. xxx; bitartrate, gr. xxx; nitrate, gr. vij; chlorate, gr. iv; permanganate, gr. j; iodide, gr. vij; bromide, gr. xv; cyanide, gr. 1/5.

The *carbonate* and *bicarbonate* are used for itching and for skin diseases; the latter is also used for dyspepsia, rheumatism, gout, jaundice, and gall stones. The *acetate* and *citrate* are used for gout, rheumatism, in dropsy, renal diseases, cardiac diseases, and in general as diuretics. The *sulphate* and *bitartrate* are used as cathartics, the latter also as a diuretic. The *nitrate* is used (by inhalations of its fumes) in asthma. The *chlorate* is used for inflammatory conditions of mouth and throat. The *permanganate* is used for wounds, sores, ulcers, erysipelas, and as a douche in gonorrhea, gleet, etc.; also as an antidote to morphine poisoning. The *bromide* is used in epilepsy, insomnia, neuralgia, migraine, delirium tremens, convulsions, nymphomania. The *iodide* is used in syphilis, asthma, chronic rheumatism. The *cyanide* is used to relieve vomiting, gastrointestinal pain, and cough.

7. *Three external antiseptics:*—For *rooms and furniture*, sulphur dioxide, generated by burning three pounds of sulphur for each 1000 cubic feet of space; for *hands of surgeon*, mercuric chloride, in solution of 1:1000; for *glassware*, dry heat at about 150° C., continued for an hour.

8. Nux Vomica. *Preparations and Doses* Extractum nucis vomicæ, gr. ¼; fluidextractum nucis vomicæ, ♏j; tinctura nucis vomicæ, ♏x; strychnine, gr. 1/64; strychinæ sulphas, gr. 1/64; strychinæ nitras, gr. 1/64. *Therapeutic indications:* As a general tonic or bitter; in indigestion, cardiac depression, impaired peristalsis, pneumonia, phthisis, amenorrhea, dysmenorrhea, impotence, some forms of paralysis, chorea, epilepsy, neuralgia, alcoholism, and urinary incontinence.

9. *Corrosive sublimate is used internally* in the treatment of diphtheria, syphilis, and as a tonic. Dose, gr. 1/100 to 1/20.

10. Opium. *Therapeutic uses:* As an anodyne, a hemostatic, in inflammations, as an expectorant, in diarrhea, in alcoholism, manias and diabetes, as an antispasmodic, in insomnia, and as a diaphoretic.

Dose: Of powdered opium, gr. j; morphine, gr. 1/5; morphine sulphate, acetate, and hydrochloride, each gr. ¼; codeine, gr. ½; codeine sulphate and phosphate, each, gr. ½.

DIAGNOSIS

1. The early manifestations of pulmonary tuberculosis are: (1) *Physical signs:* Deficient chest expansion, the phthisical chest, slight dullness or impaired resonance over one apex, fine moist rales at end of inspiration, expiration prolonged or high pitched, breathing interrupted. (2) *Symptoms:* General weakness, lassitude, dyspnea on exertion, pallor, anorexia, loss of weight, slight fever, and night sweats, hemoptysis.

2. "*Acute myocarditis* may be incident to rheumatism, pneumonia, septicemia, tuberculosis, typhoid fever, etc., and accompanies acute pericarditis and acute endocarditis. Subjective symptoms are generally absent, but the condition may be suspected when the heart begins to dilate rapidly, when the pulse becomes extremely rapid, thready, and irregular, or when the temperature suddenly rises. A systolic murmur may be heard at the apex."

"*Chronic myocarditis* results from sclerosis of the coronary arteries, but may follow acute myocarditis. The symptoms appear insidiously, and include dyspnea, palpitation, weak, rapid, and irregular pulse, anginoid pains, maniacal attacks, vomiting, etc. The area of dullness is increased. The pulmonary second sound may be accentuated if the right heart is hypertrophied, and a murmur may be heard at the apex." (*Pocket Cyclopedia of Medicine and Surgery.*)

3. *In cardiac hypertrophy* "the symptoms depend upon the amount of hypertrophy. If only sufficient to compensate for valvular defects or other circulatory disturbances there will be no symptoms. When the enlargement is disproportionate to the obstruction, it is manifested by increased and forcible cardiac action, precordial discomfort, headache, dizziness, ringing in the ears, flushes or flashes of light, dyspnea on exertion, congestion of the face and eyes, dry cough, epistaxis, and restless nights, with more or less jerking of the limbs. The arteries become full and the pulse is firm and bounding. The carotids and superficial arteries pulsate markedly, the patient frequently complaining of throbbing sensations. A sphygmographic tracing shows the line of ascent vertical and abrupt, but the apex is rounded, and the line of descent is oblique, unless there is more or less insufficiency of the valves."

In cardiac dilatation "the manifestations are referable to the enfeebled circulation and include feeble pulse, headache aggravated by the upright position, attacks of syncope, cough, dyspnea, jaundice, dyspepsia, constipation, scanty, often albuminous urine, mental dullness, vertigo, often relieved by a copious epistaxis, and finally dropsy beginning in the lower extremities. The condition terminates in death by exhaustion." (Hughes' *Practice of Medicine.*)

4. *The functional activity of each kidney* may be "determined by the intramuscular injection of 1 cc. of a 5 per cent. acqueous solution of methylene blue; the collection of the urine (from each kidney) after the lapse of one-half hour, one hour, and hourly thereafter; and noting the time of the appearance of a bluish tint to the urine, the time of maximum coloration, and the time of disappearance of the coloring. Normally a slight tint may be observed in the first specimen, certainly at the end of one hour. The maximum coloration occurs at the end of three or four hours, and the urine is free of coloring at the end of thirty-six to forty-eight or sixty hours. Delay of beginning excretion beyond one hour, and of maximum coloration beyond the fourth hour, and continuation of excretion, as may occur for five or six days, is indicative of deficient functional activity." (Kelly's *Practice of Medicine.*)

5. *Gastric ulcer* is generally caused by injury or bacteria, is most apt to occur between the ages of twenty and forty-five. After eating there is pain localized in the stomach, vomiting occurs soon after eating, hematemsis is common, there is localized tenderness over the stomach, and examination of the gastric contents shows an excess of free HCl.

In *duodenal ulcer* the pain is apt to be more to the right, and to occur at an interval of two or three hours after meals; the hemorrhages will be intestinal, and the blood will be passed by way of the bowels, and not

vomited. In many cases the symptoms are identical with those of gastric ulcer.

Cholecystitis: The pain is further to the right, and with tenderness and muscular rigidity, is referred to the region of the gall bladder; there are rise of temperature, increased pulse rate, leucocytosis, and vomiting.

6. *Hyperthyroidism* is exophthalmic goiter; the cardinal symptoms are tachycardia, exophthalmos, goiter, and tremor.

7. In *enlarged gall bladder* pain is located in the region of the liver and may radiate to the right shoulder; there may be jaundice.

In *ptosis of the right kidney* the kidney may be palpated and often replaced; the pain radiates down the ureter; chill, nausea and vomiting may be noticed; blood may be found in the urine; when the kidney is replaced all the symptoms cease.

8. *Physical signs of effusion in acute pleuritis:* There is fullness or bulging of the affected side, with obliteration of the intercostal spaces and displacement of the cardiac impulse; over the effusion there is little or no vocal fremitus, while above the effusion it is exaggerated; over the effusion the percussion note is dull, above the effusion it is tympanitic; the fluid changes its level with different positions of the body; on auscultation there will be heard a feeble vesicular murmur; vocal resonance is diminished or absent over the fluid and increased above the effusion.

9. *The most important sign of leucæmia* is a persistent increase in the total number of leucocytes.

10. *Early signs of acute poliomyelitis:* Fever; malaise; chilliness; tonsilitis, coryza, diarrhea; convulsions; profuse sweating; rigidity of head, neck and limbs; pain in neck and back. There may be *no early signs.*

PATHOLOGY

1. *In myelogenous leucæmia* the white cells are enormously increased, the red cells are decreased; the chief feature of the blood is the large number of myelocytes which it contains; the eosinophiles are also increased; so, too, are the basophiles or mast cells; the polymorphonuclears are absolutely increased, but relatively diminished as the myelocytes increase; the lymphocytes are not very numerous. The myelocytes are derived from the bone marrow.

2. *A hemorrhage infarct* is an infarct where the obstructed area is full of blood. Sooner or later the infarct becomes decolorized, owing to diffusion of the dissolved hemoglobin; the involved tissues degenerate and become absorbed; and scar tissue, more or less pigmented, may remain at the site of the lesion. Infarction is always accompanied by necrosis and fatty degeneration. Hemorrhagic infarct occurs but rarely in the kidney.

3. *Tubercle formation.*—"Miliary tubercles are tiny grayish nodules, and each consists of a collection of cells. The bacillus is brought to the tissues by a blood vessel. The bacilli set up changes in the tunica intima and the connective tissue around the vessel, which result in the formation of a collection of cells which are bigger than leucocytes. They are derived from connective-tissue cells and endothelial cells. One or more of these in each tubercle increase in size or coalesce to form a giant cell. The giant cell forms the center of the tubercle; it has many nuclei arranged around its periphery, and contains bacilli. Around it are arranged layers of epithelioid cells. Beyond these are collected many leucocytes, which merge through granulation tissue into the normal structures. The structure is not so typical in all cases, as giant cells may be absent. No blood vessels are present in tubercles, and the surrounding vessels are narrowed or obliterated by endarteritis."

Results.—"(1) *Caseation* is a result of progressive action of the bacilli. Two factors contribute to this: (1) The destructive action of the bacillus; (2) the defective blood supply from endarteritis. The center of each tubercle softens and becomes yellow or caseous. Neighboring tubercles after caseating coalesce, and a tuberculous abscess is formed and in its walls further miliary tubercles are found. (2) *Retrogressive changes.*—The resistance of the tissues is considerable, and if circumstances are favorable the bacilli are destroyed or their growth inhibited and retrogressive changes occur. The tubercle may be converted into fibrous tissue, and only a cicatrix remains; or the caseous matter may become encapsuled, and perhaps resume activity at some later date, if the capsule is ruptured by some injury. Sometimes calcification occurs. (3) *Diffusion* is a marked feature. This may be (1) local, by direct extension; (2) to distant viscera, by minute emboli; (3) acute general tuberculosis may occur in any case. Tubercles are scattered throughout the body, and the disease is fatal in a few weeks."—(*Aids to Surgery.*)

4. *Method of preparing vaccine.*—"(1) The causal organism (in this case the *Staphylococcus pyogenes*) is obtained from the seat of the lesion and isolated in pure culture at 37° C. on a suitable medium such as agar. (2) The culture growth is emulsified in about 5 c.c. of a 0.9 to 1.0 sodium chloride solution. (3) The bacterial emulsion is transferred to a water bath or incubator, and kept at 60° C. for from thirty to sixty minutes. (4) The number of bacteria in the emulsion is estimated. (5) The vaccine is diluted with normal saline solution until each cubic centimeter contains an appropriate number of organisms for the dose, *e.g.* 10 millions, 100 millions, 1,000 millions, etc. (6) The sterility of the emulsion is proved and a small amount of antiseptic, *e.g.* phenol 0.5 per cent. or tricresol 0.25 per cent., is added, and the vaccine is filled into sterile bulbs for use. In practice the bulb is opened, the contents are filled into a sterile syringe, preferably all glass, and the vaccine is injected subcutaneously under strict aseptic precautions."—(Bruce's *Materia Medica and Therapeutics.*)

5. The *physician* should wear a gown while with the patient, should inspect the patient's eyes, nose, and throat through a pane of glass so that the patient may not cough in his face, and should carefully wash his hands in an antiseptic solution before leaving. The *patient* should be isolated, and the nose, throat, and mouth should be washed with an antiseptic solution; diphtheria antitoxin should be administered as early as possible. The *family* should be kept away from the patient, and all infected articles should be soaked in a solution of corrosive sublimate or carbolic acid. The *community* is protected by the above procedure; but, in addition, the disease should be reported to the proper health authorities, other children from the family should not be allowed to go to school or church or other public places, strict quarantine must be observed, and there must be a thorough disinfection at the close of the case.

(*To be concluded.*)

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

DISEASES OF THE DIGESTIVE TRACT AND THEIR TREATMENT. By A. EVERETT AUSTIN, A.M., M.D. Published by C. V. Mosby Co., St. Louis, 1916. Eighty-five illustrations, including ten color plates. 552 pages. Price, $5.50.

DISEASES OF THE SKIN. By RICHARD L. SUTTON, M.D., Published by C. V. Mosby Co., St. Louis, 1916. Six hundred and ninety-three illustrations and eight colored plates. 916 pages. Price, $6.50.

DISEASES OF THE EYE. A handbook of ophthalmic practice for students and practitioners. By GEORGE E. DE SCHWEINITZ, M.D., LL.D. (Univ. of Pa.). Eighth edition, reset with 386 illustrations and 7 colored plates. Published by W. B. Saunders Company, Philadelphia and London, 1916. 754 pages. Price, cloth, $6.00 net; half morocco, $7.50 net.

DIAGNOSIS AND TREATMENT OF HEART DISEASE; Practical Points for Students and Practitioners. Second edition. By E. M. BROCKBANK, M.D. 120 pages, illustrated. Published by Paul B. Hoeber, New York, 1916. Price, $1.25.

EXAMINATIONS OF THE URINE AND OTHER CLINICAL SIDE-ROOM METHODS. Fifth edition. By ANDREW FERGUS HEWAT, M.B., Ch.B., M.R.C.P. Ed. 212 pages. Published by Paul B. Hoeber, New York. Price, $1.

THE PRACTICAL MEDICINE SERIES, Comprising Ten Volumes on the Year's Progress in Medicine and Surgery. Volume III, THE EYE, EAR, NOSE AND THROAT. By CASEY A. WOOD, C.M., M.D., D.C.L., ALBERT H. ANDREWS, M.D., and GEORGE E. SHAMBAUGH, M.D. Under the general editorial charge of CHARLES L. MIX, A.M., M.D. 376 pages. Published by The Year Book Publishers, Chicago, Series 1916. Price, $1.50.

A CLASSIFICATION OF THE EPILEPSIES.

BY ELIAS C. FISCHBEIN, M.D.,

SONYEA, N. Y.

CRAIG COLONY FOR EPILEPTICS.

Nomina si nescis, perit cognitio rerum (Coke).

If you do not know their names, the knowledge of things is lost.

THERE is pressing need for a new classification of the epilepsies. The nomenclature of these disease conditions has suffered from the fact that names have been applied by various authors with no adherence to any unity of scheme: "Quot homines, tot nomina"—is almost applicable to this state of affairs, that there are nearly as many names as men to do the naming. The great majority of sypmptom complexes found in this multiphase disease have had appended to them the noun "epilepsy," presumably for the sake of clearness. Unfortunately the result has been confusion. We have psychic epilepsy, tetanoid epilepsy, matutinal epilepsy, Gelineau's epilepsy, masked epilepsy, hysteroid epilepsy, etc., a state of affairs which has led to a great deal of bother and annoyance in memorizing. Each one of these has had to be remembered separately and every person interested in the study of these conditions (in order to assist his memory) has had to make a provisional working classification of his own, the latter, however, not necessarily coinciding with that of any of his contemporaries. Hence the confusion.

Epileptic attacks have been assigned as belonging to one of three groups: Grand Mal, Petit Mal, and Psychic. The difference in the implied meaning between the first and second is that "grand" refers to the matter of importance over "petit." This is true in a very limited sense only so far as the impression made upon the onlooker of a fit; but this is not so in reality. Many observers have advanced the opinion that, insofar as relates to actual injury to the brain, more damage is done by the sensory and psychic accessions. It is admitted, however, that such sensory and psychic seizures do not *appear* as severe. It was first pointed out by Esquirol,* for instance, that "transient epileptic vertigo is more damaging to the intellect than the far more violent and formidable grand mal seizures." From this standpoint the terms "grand" and "petit" are misnomers and should be abandoned.

These two names (grand and petit mal) also carry with them the sense of *severe* and *less severe*. One can appreciate the inconsistency of applying nomenclative designations which include within themselves a sense of apparent prognostic value, to disease conditions in which the prognosis is very uncertain, to say the least.

*Traite des Maladies Mentales, tome 1, p. 288.

Epilepsy, so-called, is a polyphase disease consisting of a multitude of syndrome complexes which have been found to be very nearly related one to another. In the following pages these syndromes have been grouped in classified form, the object being to fashion a classification which might follow proper scientific observance and at the same time possess such flexibility as to allow later of tentative and inductive growth.

At the present time it would be futile to attempt to classify these symptom complexes from an etiological, a pathological, or an anatomico-pathological standpoint. Our stock of information along the above lines is as yet comparatively meager, and even this is fragmentary and (apparently) uncorrelated.

The classification here presented is constructed upon clinico-symptomatological lines, the object being as far as possible to define each group sharply, to give it a name that will refer to characteristics which are constant and peculiar to that group, so that the name will be not only designatory in a conventional sense but also descriptively correct. An endeavor has been made to correlate these names so that each one may suggest its antithesis.

It seemed to the writer that in the formation of a working classification of these diseases, it would be well to use terms which, notwithstanding that they are in Latin, might be easily understood by those not especially versed in languages other than their own; recalled with little difficulty in that they have more or less relationship with the nomenclature used up to the present time, and, memorized more easily in that the classification of terms is, so far as it was possible to make it, dichotomous.

In the following schema each term is first given in Latin form, placed in its group or class and marked as follows: A Roman numeral designates the group; a Roman capital designates the class, and Arabic numerals designate subclasses. The latter are further divided into subheadings marked by either Roman or Greek letter, as the case might be. Following the classified list of epileptic syndromes is an explanation of each item under its proper designative letter or number. Certain of the terms and their place in the classification will here be explained, while at the same time the English translation and common synonyms will be given in parentheses. Other terms, the meaning of which is self-evident, will only be mentioned.

In order that there may be no misunderstanding as to the exact meaning of terms, more or less lengthy notes have been appended. The enumeration of symptoms is as brief, however, as is compatible with a clear understanding of the term. It might be added that in the explanations I have allowed myself a certain amount of latitude, this being justified by the interest shown of late in these matters.

I. PAROXYSMI* MOTORII.
- A. Paroxysmi Motorii Majori.
  - 1. *Paroxysmi Motorii Majori Vulgares.*
    - *a.* Paroxysmi Seriales.
    - *b.* Status Epilepticus (paroxysmi continui majori).
    - *c.* Paroxysmi Innocentii.
    - *d.* Paroxysmi Alcoholici.
      - α. Paroxysmi inter Bibenda.
      - β. Paroxysmi in Alcoholophilia.
      - γ. Dipsomania Aequivalens.
    - *e.* Paroxysmus Procursivus.
    - *f.* Paroxysmi Assymetrici.
      - α. Paroxysmus Unilateralis.
      - β. Paroxysmus Hemiplegicus.
      - γ. Hemiplegia Transitoria.
  - 2. *Paroxysmus Motorius Major Purus.*
  - 3. *Paroxysmi Motorii Majori Eccentrici.*
    - *a.* Paroxysmi Infantum.
      - α. Paroxysmus Infantum Eccentricus.
      - β. Paroxysmus Infantum Verus.
      - γ. Spasmophilia.
    - *b.* Paroxysmi Parturientium.
    - *c.* Paroxysmi Uraemici.
    - *d.* Paroxysmus Tetanoideus.
- *B.* Paroxysmi Motorii Minori.
  - 1. *Paroxysmus Motorius Minor Purus.*
  - 2. *Paroxysmus Minor Motorio-sensoriallis.*
  - 3. *Myoclonus.*
    - *a.* Myoclonus intermittens.
    - *b.* Myoclonus partialis continuus (Kojewnikoff).
    - *c.* Myoclonus progressivus.
  - 4. *Pseudo-myoclonus.*
  - 5. *Tetanilla.*
  - 6. *Paroxysmus Nutans.*
  - 7. *Paroxysmus Rotatorius.*
  - 8. *Paroxysmus Partialis Jacksonii.*

II. PAROXYSMI SENSORIALES.
- *A.* Paroxysmus Sensorialis Purus.
- *B.* Paroxysmus Sensorio-Motorialis.
- *C.* Vertigo.
  - 1. *Vertigo Sensorialis.*
    - *a.* Vertigo subjectiva (gyrosa).
    - *b.* Vertigo objectiva.
  - 2. *Vertigo Psychica.*
- *D.* Hemicrania.
  - 1. *Hemicrania Simplex.*
  - 2. *Hemicrania Ophthalmica.*
  - 3. *Hemicrania Æquivalens.*
- *E.* Aura *sine* Convulsione.
- *F.* Paroxysmus Thalamicus.
- *G.* Paroxysmus Vasovagosus.
- *H.* Narcolepsia.
  - 1. *Narcolepsia Vera.*
  - 2. *Narcolepsia Hysterica.*
    - *a.* Status Catalepticus.
    - *b.* Catalepsia Hysterica.
  - 3. *Paroxysmus Somnolentus.*

III. ACCESSIONES MENTIS MANIFESTÆ.
- *A.* Accessio Mentis Minor.
  - 1. *Accessio Mentis Minor Agitata.*
  - 2. *Accessio Mentis Minor Stuporosa.*
  - 3. *Accessio Mentis Minor Migrans.*
- *B.* Accessio Mentis Major.
- *C.* Accessio Hysteroidea *post convulsione.*
- *D.* Alterationes Mentis.
  - 1. *Depravatio Mentis Epileptica.*
    - *a.* Depravatio epileptica rapida.
    - *b.* Depravatio epileptica tarda.
    - *c.* Depravatio epileptica intermittens.
    - *d.* Depravatio epileptica fulminans.
  - 2. *Dementia Epileptica Vera.*

IV. ACCESSIONES MENTIS LARVATÆ.
- *A.* Poriomania (*automatisma ambulatoria*)
  - 1. *Somniatio Morbosa.*
  - 2. *Conscientia Duplex.*
    - *a.* Conscientia duplex migrans.
    - *b.* Personalitas diversa.
  - 3. *Somnambulatio.*
  - 4. *Pavor Nocturnus.*
- *B.* Status Affectus.

V. HABITUDO MENTALIS EPILEPTICA.

*I have made free use of the noun "paroxysm" in that it expresses the meaning of a sudden recurrence of symptoms and at the same time does not necessarily imply a convulsion. It is best translated by the word "seizure." Sauvages prefers this term. He refers to epilepsy as "Morbus clonicus universalis chronicus et periodicus, cum sensuum feratione in *paroxysmo* et ante actorum oblivione."

I. MOTOR CONVULSIONS.
- *A.* Major Motor Convulsions.
  - 1. *Common major motor seizures.*
    - *a.* Serial Seizures.
    - *b.* Status Epilepticus. (Continuous major paroxysms)
    - *c.* Innocuous Convulsions.
      - α. Convulsions while Drinking ("rum fits").
      - β. Epilepsy in a Drinker.
      - γ. Dipsomania as an Equivalent.
    - *e.* Procursive Seizures.
    - *f.* Assymetric Seizures.
      - α. Unilateral Convulsion.
      - β. Convulsion followed by Hemiplegia.
      - γ. Transitory Hemiplegia.
  - 2. *Pure Major Motor Convulsion.*
  - 3. *Reflex Major Motor Convulsions.*
    - *a.* Infantile convulsions.
      - α. Reflex infantile convulsions.
      - β. True (epileptic) infantile convulsions.
      - γ. Spasmophilia.
    - *b.* Eclamptic Convulsions.
    - *c.* Uremic Convulsions.
    - *d.* Tetanoid Convulsions.
- *B.* Minor Motor Convulsions.
  - 1. *Pure Minor Motor Seizure.*
  - 2. *Minor Motor-sensory Seizure.*
  - 3. *Myoclonus.*
    - *a.* Intermittent myoclonus.
    - *b.* Localized and continuous myoclonus.
    - *c.* Progressive myoclonus.
  - 4. *Pseudo-myoclonus.*
  - 5. *Tetany.*
  - 6. *Nodding Spasm.*
  - 7. *Rotary Spasm.*
  - 8. *Jacksonian Convulsion.*

II. SENSORY SEIZURES.
- *A.* Pure Sensory Seizure.
- *B.* Sensory-Motor Seizure.
- *C.* Vertigo.
  - 1. *Sensory Vertigo.*
    - *a.* Subjective vertigo.
    - *b.* Objective vertigo.
  - 2. *Psychic Vertigo.*
- *D.* Hemicrania.
  - 1. *Simple Hemicrania.*
  - 2. *Ophthalmic Hemicrania.*
  - 3. *Hemicrania as an Equivalent.*
- *E.* The Aura Without a Convulsion.
- *F.* Thalamic Seizure.
- *G.* Vaso-vagal Attack.
- *H.* Narcolepsy.
  - 1. *True Narcolepsy* (Gelineau's).
  - 2. *Hysterical Narcolepsy.*
    - *a.* Status Catalepticus (in an epileptic).
    - *b.* Hysterical catalepsy (in a non-epileptic).
  - 3. *Somnolent Attack* (a minor sensory seizure).

III. FRANK MENTAL ACCESSIONS.
- *A.* Minor Mental Accession.
  - 1. *Minor Mental Accession with Excitement.*
  - 2. *Minor Mental Accession with Stupor.*
  - 3. *Minor Mental Accession with Wandering.*
- *B.* Major Mental Accession (*"epileptic mania"*).
- *C.* Hysteroid Convulsion *following an epileptic.*
- *D.* Mental Changes.
  - 1. *Epileptic Mental Deterioration.*
    - *a.* Rapid.
    - *b.* Slow.
    - *c.* Intermittent.
    - *d.* Fulminant.
  - 2. *Epileptic Dementia.*

IV. MASKED MENTAL ACCESSIONS.
- *A.* Poriomania (*ambulatory automatism*)
  - 1. *Dream States.*
  - 2. *Dual Consciousness.*
    - *a.* Dual consciousness, with wandering.
    - *b.* Diverse personality.
  - 3. *Somnambulism.*
  - 4. *Pavor* (night terrors).
- *B.* Status Affectus (*psychogenic epilepsy*).

V. EPILEPTIC CHARACTER.

EXPLANATION OF SCHEMA.

I. Paroxysmi Motorii (motor seizures) in which the most striking symptom is violent contraction, or series of contractions, of muscles.

A. Paroxysmus Motorius Major (major motor seizure).

1. *Paroxysmus Motorius Major Vulgaris* (ordinary major motor seizure). This is the common major motor seizure, the one which of all other attacks, occurs most frequently. This type may alternate with other forms of seizure in the same individual. Usually any given major motor seizure in an individual is an exact replica of the seizure preceding it. It must be remembered that there may be differences in onset and general characteristic in various persons, therefore a composite picture of the common major motor seizure will here be very briefly outlined:

Aura; initial cry; loss of consciousness; fall; tonic spasm; deviation of eyes and face; flexion of head toward one or other shoulder; cyanosis and engorgement of face; insensitiveness of conjunctivæ; cessation of breathing for several seconds; clonic spasm, stertorous breathing, biting of tongue; frothy, blood-stained saliva on lips; initial contraction with, later, wide dilatation of pupils, nonreactive to light; involuntary passage of urine, more rarely, of feces; post-convlusive coma and later, headache; transient weakness of one or more limbs, rarely paralyses; mental confusion for a variable length of time.

There are variations of this syndrome depending on special manifestations of symptom grouping before, after or during the seizure. The most common aside from the above will now be briefly discussed.

a. Paroxysmi Seriales (serial seizures). This term needs no explanation nor does the condition require elaboration as it is a very common occurrence.

b. Status Epilepticus (Paroxysmi Continui Majori; continuing major motor seizures). The old name is retained because usage has made it represent a typical picture. The more descriptive term "Paroxysmi Continui Majori," is, however, here suggested.

c. Paroxysmi Innocentii (innocuous convulsions). This term is here introduced, not because there is any difference in character between these and common major motor seizures, but in order to focus attention on the fact that a certain small percentage of epileptics have their attacks without apparent subsequent mental deterioriation. These individuals, however, do show a certain modicum of degenerative psychic abnormality. As to whether the latter is causative or resultant with regard to the epilepsy is an open question. In this class are included people who rank intellectually high (Napoleon, Cæsar, Mahomed, Ann Lee, etc.).

d. Paroxysmi Alcoholici (alcoholic epilepsy; alcoholic seizures). The use of the term alcoholic epilepsy has resulted in a great deal of confusion. It actually includes three types of seizures associated with alcoholic indulgence and the promiscuous application of the term to all three is the cause of much ambiguity. The three types are:

α. Paroxysmi inter bibenda (convulsions while drinking; "rum fits"). Attacks occurring *only* when the patient resorts to drinking. Seizures disappear during abstinence, and there is usually no mental deterioration. This type is in close relation with delirium tremens and approaches a psychotic condition on an alcoholic basis.

β. Paroxysmi in Alcoholophilia (convulsions occurring in a person exhibiting alcohol-desire). In other words, epilepsy occurring in a drinker. Attacks *do* occur during periods of abstinence; the case shows a progressive course, periodic moods, irritability, etc.—*i.e.* the epileptic character. This type represents a pure epilepsy occurring in an alcoholic.

γ. Dipsomania æquivalens (epileptic dipsomania). A rather rare condition in which the drinking debauches are really epileptic equivalents.

e. Paroxysmus Procursivus ("epilepsia cursiva" of Boötius; procursive epilepsy). This form exhibits peculiarity in that the epileptic will, immediately before the fit, run forward 20 or 30 feet or he may run around in a circle and then fall in the seizure. Otherwise this type is exactly similar to the common major motor attack. It is mentioned here only that it may represent the entire group of major motor seizures which approach in type the common form with the exception of one or several abnormal characteristics. I will only mention a few of these: Paroxysmus retropulsivus (with running backward before the seizure), P. gyratorius (rolling on the ground), P. uncinatus (aura of sight, smell, etc.), P. analepticus (gastric aura rising to head), etc.

f. Paroxysmi Assymetrici (assymetric seizures). The term "hemiplegic epilepsy" has been applied to various conditions. There are three distinct types, and the fact that the same term is used for all three has of necessity resulted in ambiguity. A convulsion which has unilateral distribution is called hemiplegic epilepsy (Bravais); as seen in the schema it is here termed "paroxysmus unilateralis."

There is another form of so-called hemiplegic epilepsy in which, following a convulsion, there is permanent paralysis of one side. This form is here termed "paroxysmus hemiplegicus."

A third type is that in which an individual with the Habitudo Mentalis Epileptica (epileptic mental make-up), has episodic occurrences of hemiplegia with or without the concurrence of convulsions, and in whom the hemiplegia later disappears. This form is also usually referred to as hemiplegic epilepsy. In this classification the type is called "Hemiplegia transitoria." Although this is not a paroxysm in the full sense of the word, it is here interpolated on account of its confusion with other types of assymetric epileptic attacks. (Vide "Somniatio Morbosa," group IV.)

One more type must be mentioned only to be excluded from this group, and that is Paroxysmus Partialis Jacksonii, which is often referred to as hemiplegic epilepsy, an absolute misnomer. (See B, 6.)

2. *Paroxysmus Motorius Major Purus* (pure major motor seizure; conscious epilepsy). A major motor seizure in which the sensorium is, wholly or in part, free from involvement. There is retention of consciousness in whole or in part. L. Pierce Clark has reported three cases and quotes Lemoine, Radcliffe, Tamburini, and several others who have reported this type of attack. In the Craig Colony for Epileptics there are at present two patients who show pure major motor attacks of modified form. The occurrence of this type is rare, but it serves as an excellent illustration of involvement of musculature only and exemption of the sensorium.

3. *Paroxysmi Motorii Majori Eccentrici* (reflex major motor seizures).

a. Paroxysmi Infantum (convulsions of infants; eclampsia infantum; infantile convulsions). Infantile convulsions may be of two distinct types.

α. Paroxysmus Infantum Eccentricus (reflex infantile convulsion). The infant may be of normal physical and mental make-up, but there may occur temporary reflex disturbance of the very sensitive nervous organism. Such disturbance may be caused by gastrointestinal disorder, fevers which involve the brain and its matrices, diarrhea resulting from dentition or worms, etc. On the other hand, one may see a

β. Paroxymus Infantum verus (true infantile convulsion). Occurring in an infant which *is really an epileptic*, and in which the paroxysm is only one of many which have occurred before or will occur later.

Aside from these two types we must take into consideration the type which, though not epileptic, is still affected with a certain nueropathic constitutional instability. This is manifested by hyperexcitabiiity of the peripheral nervous system, resulting in tendency to tonic and clonic spasms (chorea, laryngismus stridulus, tetany, apnea, carpopedal contractions, etc.). To this condition has been given the name "Spasmophilia" or the spasmophilic diathesis. Phenomena coming under the group of spasmophilias should be distinguished from true epileptic paroxysms, as they have not been proven to be strictly epileptic in nature.

b. Paroxysmi Parturientium (puerperal convulsions; eclampsia gravidarum). Common major motor seizures upon a uremic basis.

c. Paroxysmi Uræmici (uremic convulsions). At times these attacks cannot be distinguished symptomatically from the common major motor seizures. They occur in nephritis with its concomitant symptoms. There is usually no intial cry. The onset is sudden. Convulsions may occur every hour or two and there is deep coma between attacks. Following such seizure or series of attacks there may be coma persisting for several days or weeks. There may be amaurosis without visible retinal lesion and there may be development of mono- or diplegia.

d. Paroxysmus Tetanoideus (tetanoid epilepsy). A type of major motor seizure in which there is tonic contraction only, of muscles. The individual may lose consciousness and fall, going immediately into tonic contraction and then recovering. Sometimes the epileptic does not fall, but goes into a tonic spasm for several moments and then relaxes, recovered. A severe type of this condition which is comparatively rare has been described by Pritchard.

B. Paroxsmi Motorii Minori (minor motor seizures), as distinguished from the severer type mentioned under Class A. These types are often found associated with other forms of epileptic accessions in the same individual.

1. *Paroxysmus Motorius Minor Purus* (pure minor motor seizure; "jerks"; "starts"), characterized by twitching and jerking of muscles in groups without loss of consciousness. Of common occurrence in frank epileptics. Often seen immediately before a major motor seizure.

2. *Paroxysmus Minor Motorio-sensorialis* (minor motor-sensory seizure, in which the motor phenomena predominate. In general the individual may be said to become suddenly semi-rigid, eyes stare, pupils dilate slightly, one or other limb is flexed or extended, respiration is difficult for a moment, and then recovery. He may have an aura before the attack and there may be semi-stupor with purposeless and automatic acts following. The paroxysm itself usually lasts not more than several seconds.

3. *Myoclonus* (paramyoclonus multiplex of Friedreich; choreic tics; multiple tics; myoclonus spinalis multiplex; myokymia). This term, which is in common use, meets our needs. It so happens that myoclonus and its modified forms is one of the few syndromes properly cognomenated. Briefly the distinguishing features of this affection are lightning-like contractions of groups of muscles. The contractions may involve only one group of muscles or the whole body. Consciousness is not lost. They may occur as epiphenomena to major or minor seizures, or as an uncombined symptom complex. These contractions may also involve one group of muscles, later extending to the whole body musculature and, in certain instances, terminate in a major motor seizure. The following terms are already in use and should be adhered to: (*a*) Myoclonus intermittens, (*b*) myoclonus partialis continuus (Kojewnikoff's epilepsy), and (*c*) myoclonus progressivus (syndrome of Unverricht and Lundborg). The names are descriptively correct and self-explanatory.

4. *Pseudomyoclonus.* Single or multiple myospasmias on a hysteric or choreic basis. The name has also been applied to the sudden localized muscular contractions seen immediately before major motor seizures, but these must be regarded as part of the aura.

5. *Tetanilla* (tetany) is mentioned here only as a reminder that it occurs in relation with epilepsy and often requires diagnostic consideration. The three important clinical types are (*a*) Tetanilla gravidarum, (*b*) T. rhachitica, (*c*) T. thyreopriva.

6. *Paroxysmus nutans* (nodding spasm; salaam convulsion). A peculiar bobbing of the head forward. It is found most frequently in children. Often the child, while sitting at table, will have a seizure of this type and strike the table chin first. This form of minor motor seizure was first described by Sir Charles Clark.

7. *Paroxysmus Rotatorius* (Dervish spinning; "whirling Dervish"). A type of minor motor seizure in which the individual (usually a child), does not fall but spins about on one or othe other foot for from several seconds to several minutes. In this form consciousness is not entirely lost but considerably obtunded. This name should not be confused with Paroxysmus gyratorius (see I, A, *i.e.* P. procursivus); in the gyratory paroxysm, which is a major motor type, the individual after falling to the ground, rolls about, over and over until the tonic state reaches its height.

8. *Paroxysmus Partialis Jacksonii* (Jacksonian epilepsy; hemiplegic epilepsy; cortical epilepsy; symptomatic epilepsy). The chief characteristic of this form of convulsion is its localization to a certain set of muscles. This localization of the fit does not change. It must be remembered that a symptomatic convulsion is not necessarily a Jacksonian seizure. In a general way paroxysmus partialis Jacksonii is a type of localized convulsion limited either to one side of the body or to one set of muscles; consciousness is not lost. The convulsions are due to reflex causes, *i.e.* cerebral abscess, hemorrhage, cicatrix, or tumor. It is also seen in relation with uremia, paralytic dementia, and alcoholic excess. At times the convulsion begins as the usual

focal one, but spreads so as to involve other muscles and ends with a typical major motor seizure. There has of late years been a tendency to do away with eponyms in medical literature. While in perfect accord with this trend, the writer feels that the work of Hughlings Jackson in the field of epilepsy has been of such value that his name should be associated with the form he first described.

Up to this point we have been discussing myospasmias, *i.e.* those incidents in the epilepsies which are chracterized by spasmodic muscular contractions. We now come to several groups in which convulsions do not play a prominent rôle. The following series of syndromes are divided into sensory and mental (psychic) accessions.

II. Paroxysmi Sensoriales (sensory seizures). Those paroxysms which involve the sensorium wholly or in part, but which are sudden in onset and of short duration, with either unconsciousness or the cognition of pain, vertigo, ideas, sensations, reminiscences, etc., on the part of the individual.

A. Paroxysmus Sensorialis Purus (pure sensory seizure; "faints"; "loss"). The individual becomes suddenly pale, his eyes stare, and the seizure is over. This type may occur alone or in the form of an aura (see Aura sine convulsione, II. E.). The characteristic of this form is a periodic, transitory disturbance of consciousness.

B. Paroxysmus Sensorio-motorialis (sensory motor attack). In this a pure sensory seizure is accompanied by slight muscular spasms and contractions. A common form.

C. Vertigo (circumgyratio; giddiness; dizziness). A rather frequent episode in epilepsy characterized by a sense of instability of either the subject himself, or by apparent lack of stability of objects about him. Due to disturbance of either epicritic or protopathic sensibility on the one hand, or to disturbance of associative subconscious impulses on the other. Disease or disturbed function of the labyrinth, eyes, skin, stomach, muscles, tendons, and joints may result in erroneous mental conception as to position in space. There are two main types.

1. *Vertigo Sensorialis* (sensorial vertigo). This may be either subjective (vertigo gyrosa), or objective, and is the result of confusion of function on the part of the associative paths upon which the individual normally depends to recognize his position in space.

a. Vertigo subjectiva (gyrosa). The individual feels himself falling, floating or spinning around.

b. Vertigo objectiva. In which the surrounding objects appear to move.

2. *Vertigo Psychica* (psychic vertigo). A sensation of disturbance of equilibrium brought on by agitating thoughts, memory pictures, and emotions. These disturbing thoughts, emotions, and memories cause the same confusion in mental association as was mentioned in connection with sensory vertigo.

D. Hemicrania (megrim; migraine; cephalalgia; neuralgia cerebralis). This type of nervous disturbance occurs either in relation to a seizure, as an equivalent or unaccompanied by attacks. The headache, although termed "hemicrania," never occurs as exactly confined to one side; but it is usually *felt* as more severe on one side than on the other. Migraine resembles epilepsy in several ways. Both are hereditary. Both are periodic in point of occurrence. Both may show an aura. Migraine may be replaced by a psychic equivalent, like any epileptic attack. Both migraine and epileptic seizures are followed by somnolence. Epilepsy may exist synchronously with migraine in the same individual. Epileptic seizures may be replaced by attacks of migraine and vice versa. Three well-marked types exist.

1. *Hemicrania Simplex* (simple migraine). Attacks are periodic and followed by somnolence. They usually persist during the life of the individual.

2. *Hemicrania Ophthalmica* (ophthalmic migraine). In this form the migraine is associated with visual disturbances, spectral, and objective, *i.e.* hemianopsia, scintillating scotoma, amaurosis, ocular palsies, etc.

3. *Hemicrania Æquivalens* (h. occurring as an equivalent). This may be the only symptom for years, later to be replaced by true epileptic attacks. (In such cases to be regarded as a larvate form).

E. Aura sine Convulsione (aura without a convulsion). This form of occurrence should be regarded as a pure minor sensory attack. The subjective symptomatology of the various auræ is extremely diverse, but for the sake of explicitness several common types will be referred to.

1. *The analeptic aura*: a sensation or "feeling" which subjectively seems to start in the region of the stomach and ascends rapidly to the head.

2. *The "familiarity" type*: in which the individual has the mental impression of being in surroundings or of going through a mental conception, that seems to have been experienced at some previous time.

3. *The "strangeness" type*: a certain subconscious complex is allowed to come to the surface and produces an impression of strangeness and incongruity with the surroundings.

4. *The "visual" type*: flashes of light and color, especially blue, violet, and red. Reminiscences of scenes, animals, pictures, etc. There are many other forms; special sense auræ, auditory, olfactory, gustatory, etc. Any of the above should be regarded as sensory seizures when not accompanied by convulsions.

F. Paroxysmus Thalamicus (sensory epilepsy; thalamic epilepsy). A minor sensory episode in which there are delusions of sight, hearing, or smell and in which there are also hallucinations. Usually occurs as an equivalent to seizures. This type is thought to be due to organic involvement of the thalami.

G. Paroxysmus Vasovagosus (vagal attack; vasovagal attack). First described by Sir William Gowers. Consists of sudden and periodic attacks of headache and dyspnea followed by somnolence; sudden waking from this sleep with a sense of suffocation, wild beating of the heart, and rigor. This in turn is followed by flushing and a feeling of warmth; the attack is over. There may be absence of the period of somnolence. This condition is existent upon an epileptic basis.

H. Narcolepsia (narcolepsy). A disease condition characterized by recurring somnolence. Thought to be due to disturbance of the hormone secretion of the anterior hypophyseal lobe. This condition was first scientifically described by Gelineau and later by Friedman. Five conditions are to be taken into consideration:

1. *Narcolepsia Vera* (true narcolepsy; Gelineau's epilepsy). This form is of very rare occurrence, but epileptic in nature. A sudden onset of apparently true sleep lasting about five to ten minues, occuring at any time of day and showing periodicity

in matter of recurrence. Not followed by headache.

2. *Narcolepsia Hysterica* (hysteroid narcolepsy). This form may occur in epileptics in the form of Status Catalepticus, or in non-epileptics in the form of trance. Therefore we have

a. Status Catalepticus (catalepsy, stupor vigilans, catochus, etc.). A hysterical form of narcolepsy observed in epileptics. Hysteroid in nature and probably not dependent upon the condition causing the epilepsy. In this occurrence there is a sudden suspension of the action of the senses and of consciousness with great muscular plasticity, the limbs and trunk preserving the different positions given to them. A rather rare condition.

b. Catalepsia hysterica (trance; ectasis). A condition which is purely hysterical and not in relation with epilepsy. Consists of sleep episodes which last for days and weeks. Interpolated here for differentiation.

3. *Paroxysmus Somnolentus* (sleep attack). A true minor sensory seizure in which the only marked symptom is somnolence. This type occurs in epileptics with comparative frequency and should be sharply distinguished from narcolepsy, which is a rare condition.

We will now take into consideration the mental accessions. These may be either frank (manifest) or masked (larvate).

III. Accessiones Mentis* Manifestæ (frank mental accessions).

A. Accessio Mentis Minor (minor mental accession; intellectual Petit Mal). This form is one of the epiphenomena to seizures. It may occur before or after a seizure; it may also occur as an equivalent. There are three types:

1. *Accessio Mentis Minor Agitata* (excited minor mental accession; mental disturbance). There may be a sensory aura consisting of one of the uncinate group (smell, hallucinations of sight or hearing, unusual brightness of objects, etc.). There may be some vertigo. The individual becomes despondent, he is aware of difficulty in collecting his thoughts and of fixing his attention. Volition is lost and there are certain uncontrollable impulses, which may cause him to commit any form of violence, theft, homicide, suicide, arson, etc. Sometimes ecstatic visions or sounds are experienced in this stage (cenesthesis).

This attack is of comparatively short duration, several minutes to an hour or so. It may culminate in some act of violence following which the epileptic recovers with practically total amnesia for all the incidents which had occurred.

2. *Accessio Mentis Minor Stuporosa* (stuporous minor mental accession; "mental confusion"). This form presents a stuporous condition, sometimes even amounting to a lethargy; pupils slightly dilated, lack of orientation and insight, verbigeration of set phrases, and purposeless automatic movements. This picture of epileptic mental confusion is very common following seizures or as an equivalent to them.

3. *Accessio Mentis Minor Migrans* (wandering minor mental accession). This form may occur as an equivalent to a seizure or, more often, following an attack. The individual wanders about aimlessly and if molested resists to the point of violence. Sometimes the epileptic will have this type of accession during the night, in which case he will rise from bed and wander away, barefoot and unclothed. His wanderings end only when the period of somnolence, which forms the terminal stage of this condition, claims him. He will often be found on the street or in the fields, as the case may be, while in this somnolent state.

B. Accessio Mentis Major (major mental accession; epileptic mania; extreme mental disturbance; epilepsia furiosa). This form may be pre- or post-paroxysmal; it may also occur as an equivalent. The onset is usually sudden in which respect it resembles a major motor seizure. There are cases, however, in which the onset is preceded by extreme headache or vertigo with vomiting; there may be slight spastic movements of limbs or muscles of the face. Emotionally one sees either depression or some excitement, and often irritability. Within an hour or perhaps a few hours there is an explosion into a full blown mania. The epileptic may cry, yell, or bite and tear at his bedclothes. In some cases he talks or shouts incessantly, unintelligible jargon or stereotyped phrases. Some epileptics show evidences of hallucinations of sight or hearing which cause fear and dread. Mental episodes of this kind are very often followed by rapid and profound mental deterioration. Following the accession there is usually stupor and after recovery, total amnesia.

While discussing this subject attention might be drawn to a condition not at all uncommon and which we can for convenience term "Mania transitoria liberorum," *i.e.* transitory mania of children. Maudsley has remarked that, "In children, as well as in adults, brief attacks of violent mania, a genuine mania transitoria, may precede, or follow, or take the place of an epileptic fit; in the latter case being a masked epilepsy. Children of three or four years of age are sometimes seized with attacks of violent shrieking, desperate stubbornness, or furious rage, when they bite, tear, kick, and do all the destruction they can; these seizures, which are a sort of vicarious epilepsy, come on periodically and may either pass in the course of a few months into regular epilepsy or may alternate with it."

I put this type of epileptic episode under the heading of major mental accessions in order that it may be more easily remembered. It might, with reason, however, be put with the Affect form. Occurring, as it does, in young children and of apparently psychogenetic origin, the consideration of this type brings us into the domain of "Mutterleibtrieb" recently expounded by L. Pierce Clark in his paper on Affect Epilepsy.*

C. Accessio Hysteroidea Post Convulsione (hysteroid attack following an epileptic convulsion). Usually occurs after minor motor seizures. The result of an unstable condition of the psyche, such as is found in pure hysteria, combined with inactivity of the higher centers as the result of the effect of epileptic seizures; the lower centers are thereby released from higher inhibitory control, and the result is a convulsive episode closely resembling a major or minor motor attack.

D. Alterationes Mentis (mental changes).

1. *Depravatio Mentis Epileptica* (epileptic men-

*Considered psychologically, sensory and motor phenomena are also mental processes. The designatory term "mental" is here used in a conventional sense only.

*While one need not accept *in toto* the ideas promulgated by the Freudian disciples with regard to the relationship between sexuality and these forms, still one is forced to wonder whether there are not certain grounds for belief that there is *some* connection between sexuality and epilepsy. I might here cite the well-known observation accredited to Hippocrates—ἡν συνουσίαν εἶναι μικρὰν ἐπιληψίαν.

tal deterioration). A retrograde change in the associative, attentive, and perceptive faculties, the result of the effects of epileptic accessions (motor, sensory, or psychic) upon the intellect (see Habitudo mentalis epileptica). Depending upon the course of deterioration, four types exist:

a. Depravatio Epileptica Rapida (rapid mental deterioration), in which there is appreciable failing of intellect in the course of from several months to a year.

b. Depravatio Epileptic Tarda (slow epileptic mental deterioration), in which the course of deterioration is prolonged over a length of time extending from one year to several years. This type usually shows gradual merging into dementia epileptica. This form of deterioration is the most common and is marked by one special feature, *i.e.* failure in the perceptive faculty. The sphere of perception shows unsettlement in one or more of three different ways: retardation and difficulty of perception, breaks in perception, and falsifying of perception.

α. Retardation and difficult of perception: results in restriction of thought association and therefore poverty, narrowing and slowness of ideation; prolonged reaction time. This in turn leads to stereoptypy, perseveration, and circumstantiality.

β. Breaks in perception: lead to twilight states, fugues, absences, etc.

γ. Falsifying of perception: leads to impulsiveness, delusions and hallucinations.

c. Depravatio Epileptica Intermittens (intermittent epileptic deterioration), in which there is a certain amount of mental failure for a length of time followed by standstill as regards deterioration. Later there is a continuation of mental failure.

d. Depravatio Epileptica Fulminans (fulminant epileptic deterioration). A rare type. Within the short period of three or four days, more or less, the individual's mental condition changes from perhaps fair intelligence to that of low grade dementia. This phenomenon may be comitial to seizures or may occur aside from attacks.

2. *Dementia Epileptica Vera* (true epileptic dementia). This form must be distinguished from paralytic and senile dementia, from dementia præcox, idiocy, imbecility, and the epiphenomena to seizures. The affection is slow and progressive. It is seen in a comparatively large number of epileptics, especially so in those in whom the onset of the disease occurs late in life. Judgment and reason are lost wholly or in part. Attention becomes poor and memory is weakened. Orientation is poor in all respects. Mental confusion is more or less constant; delusions are common. There may be changes in the voice as to modulation, inflection, clearness of articulation and pitch. These voice changes in the form of "plateau speech" collectively form a syndrome often found in those showing epileptic affectivity. The dementia is multiform as to symptoms and there are different types which assume special character depending on the course (slow, rapid, or intermittent), or on the accompanying complications (paralyses, contractures, pseudo-paralyses, etc.

IV. Accessiones Mentis Larvatæ (masked mental accessions; "psychic epilepsy"; masked epilepsy).

A. Poriomania (ambulatory automatism).

1. *Somniatio Morbosa* (disease dream; dream state; twilight state; "absence"; Dämmerzustand; "fugue"; crepuscular state). This type of mental accession occurs as an equivalent to seizures in the frank forms of epilepsy or, more commonly, as a periodically recurring mental episode in the larvate forms. The condition is polyphase in its manifestations. The "dream state" may recur in exact duplicature or vary as to character of events in the same individual. The condition comes on suddenly and ends suddenly with either return to the usual condition or with somnolence and headache. Many citations might here be given of these conditions, but as I am endeavoring to make these explanations of terms as briefly definitive as possible, two types only will be briefly mentioned (taken from A. V. Goss):

a. Partial Aphasia coming on suddenly after nervous strain. Unconsciousness for an hour or two. Existence for ten days with partial loss of memory for past events and persons; sudden recovery with complete restoration of memory for everything, but complete amnesia for occurrences during the ten days.

b. A condition allied to somnambulism as well as to "Hemiplegia transitoria." The patient falls asleep and in ten to twenty seconds he awakens to find himself paralyzed in one or more limbs. A few seconds later the paralysis passes off, the episode is over.

It must be remembered that the above two episodes are not *typical* of dream states, as each individual experiences heterologous arrangement of mental concepts and events peculiar to himself.

2. *Conscienta Duplex* (double personality; dual consciousness; dissociated personality). There are at least two well-defined types:

a. Conscienta Duplex Migrans (dual consciousness with wandering). The type of occurrence in which the individual will, without external manifestation of mental aberration, wander away from his home and town, spend days, weeks or months in a new environment. He conducts himself either peaceably or not as the case may be. Later he returns to his original personality with total amnesia for the entire period just gone through.

b. Personalitas Diversa (diverse personality; heterogeneous personality). An individual, let us call him "A," suddenly changes his state of conscious being to that of an individual having an entirely different mental make-up. From a person, let us say, of studious, serious, introspective character, there is evolved a personality shallow-minded, bright, cheerful, and care-free. We will call this latter "B." The last personality may obtrude itself on the first at periodic intervals, without warning and at any untimely moment. These invasions on one personality by another are therefore seen to partake of the character of an epileptic attack. This form of accession may occur in a frank epileptic as an equivalent to a seizure. Usually it is a larvated accession in an individual who shows no other marked symptoms of epilepsy, but who may later show up as a masked type. Cases are on record in which there have been obtrusions of two or even three personalities upon the so-called normal one. One more point should be noted in the discussion of this type; that while these episodes occur in persons who are neuropathically tainted and who may later develop epilepsy, still they may occur in people *who are not epileptics.*

Under the heading of disease dream (somniatio morbosa) the following two conditions must also be considered:

3. *Somnambulatio* (somnambulism; sleep-walk-

ing). A periodically recurring and temporary suspension of volition and consciousness, usually accompanied by automatic acts. A morbid disease entity on the borderline between epilepsy and hysteria. "Dr. Darwin was, I believe, the first to advance the idea that somnambulism is nearly related to epilepsy; incubus he also regards as related to both somnambulism and epilepsy." (Pritchard in his "Diseases of the Nervous System.")

4. *Pavor Noeturnus* (night-terror). Commonly seen in children. In a case of this kind the child awakes two or three hours after falling asleep. It screams in terror and is apparently unable to recognize anyone; during this period the child may get up from bed and run about in a frenzy of fear as though trying to escape from something which was frightening it. This form is rather serious in import, as it indicates an unstable nervous constitution and may be the forerunner of a subsequent epilepsy.

B. Status Affectus (psychogenic epilepsy; affect epilepsy; emotional epilepsy; masked epilepsy). One often finds a mixture of the classic form of major motor seizure with psychoneurotic episodes. These latter may be found in a frank epileptic as equivalents. When, however, they occur in an individual who *does not* have epileptic seizures, these episodes combined with a peculiar constitutionally neuropsychopathic mental make-up form the condition which has been termed the "affect" or psychic form of epilepsy by Bratz and Leubuscher.

Without somatic reason, and in individuals who are really hereditary neuropathic and psychopathic degenerates and who, we have reason to believe, are highly reactionary to environmental psychic stimuli, occur periodic attacks of dizziness, "fainting spells," temporary losses of consciousness, auditory and visual hallucinations, maniacal seizures, delusions and suicidal attemps. There also occur disorientations which last variable lengths of time. Often one sees attacks simulating those of true epileptic type, somewhat less severe perhaps, and usually brought on by external excitation or insult. There is no, or very little, deterioration in these cases. They do not go into status and very rarely do they have series of seizures; when they do, however, the number of convulsions is small. They do not as a rule injure themselves in attacks, and death in a seizure does not occur.

V. Habitudo Mentalis Epileptica (epileptic mental make-up; epileptic character). A peculiar mental state, the result of exogenous stress upon a mind ontogenetically and phylogenetically abnormal. There are found perversions of emotion, judgment and memory, also certain contraventions of normal conduct as the result of egocentricity, religiosity, and disordered moral criteria. In order that these inversions may be better remembered I will here put them down in classified form.

1. *Emotional Sphere.*—Shows marked instability, irritability, and hypersensitiveness.

a. Instability—leading to lack of inhibition; capriciousness in moods with changes that are instantaneous; *i.e.* alternation of despondency with elation, obstinacy with docility, taciturnity and loquaciousness, defiance and obsequiousness, etc. Hysteria may also be a complicating factor.

b. Irritability—leading to sudden, passionate and impulsive transports of rage and violence, or to excesses in venery or alcoholism.

c. Hypersensitiveness—leading to optimism, affection, pessimism, hatred, suspicion and jealousy.

2. *Judgment.*—As a class epileptics show one form of judgment almost exclusively (and that in modified form), namely, *esthetic judgment.* This form is characterized by appeal to the emotional side of consciousness and cannot be defined in terms that might be apprehended by the intellect. This, as opposed to *scientific esthetics* in which the ideal or standard may be described, analyzed and defined in terms of its factors. An epileptic of everyday type who shows a little deterioration only, forms opinions by "feeling," *i.e.* emotion. As regards his conceptive determinations, there is not necessarily any inference or ideal standard, of either excellence or deficiency. Therefore, decisions made by him are often erroneous. This accounts for his poor ability to adapt himself to his environment, either topographical or social.

3. Memory.—Primary identification (involving the senses) is fairly good as a rule. Secondary identification (involving reminiscences, images, mental concepts, etc.) is usually quite poor. Amnesias and paramnesias are of frequent occurrence. Another peculiarity of epileptics is, that matters of general information are easily forgotten, but those things which relate to personal affairs and interests are well retained, *i.e.* ipsocentric memory sphere.

4. *Egocentricity.*—One finds two marked factors:

a. Unsociality—as evinced by quarrelsomeness uncontrollable temper, moroseness, obstinacy, arrogance, conceit and boasting.

b. Self-consciousness—of high degree, as shown by egocentric narrowing of the sphere of interest and thought, magnification of his own importance, self-assuredness; also a combination of the "know-it-all" attitude with, at the same time, self-depreciation.

5. *Religiosity.*—Bible-reading and piety which is often hypocritical; religiousness in contrast to depraved ethical standards in the same individual.

6. *Moral Sphere.*—Stigmatized by various degrees of fabrication, subterfuge, truculence, malice, coprolalia and sexual perversions, as opposed to piety and beneficence in the same person.

One often hears the statement, in referring to a patient's seizures, "He has grand mal attacks." The presumption is that by this remark is meant, that the individual in question is having major motor attacks. A glance at the classification shows that there are sixteen different kinds of major seizures. Such a remark is therefore seen to lack preciseness. The classification also takes into consideration ten minor motor types, fourteen sensory types, seven manifest psychic, and seven larvate psychic incidents. These fifty-four types represent the most important forms of epileptic episodes. There are modifications of many of these, but any such modification can easily be put in its proper place in the schema.

THE CLINICAL MANIFESTATIONS OF ANIMAL PROTEIN POISONING.

By ROBERT CURTIS BROWN, M.D.,

MILWAUKEE, WIS.

We might divide all the diseases to which mankind is subject, as Herbert Spencer does his philosophy, into the known and the unknown.

Of the known diseases the principal ones are those due to infection. Of these the causes are well understood, and a suitable prophylaxis may be provided. It is of those diseases of obscure origin, of which many causes have been suggested, but none accepted that I am going to speak.

Much has been written about the cause of gout, but there is only one thing in regard to gout of which we are certain, and that is, if we give a gouty person an excess of protein food the nitrogen excretion does not rise abruptly and fall abruptly, as in a normal person, but it rises slowly and falls slowly, that is, the metabolism is delayed.

I have found by experience on myself and others that certain gouty manifestations such as headache, neuralgia, myalgia, arthritis and certain skin and mucus membrane manifestations can be brought on by eating meat, meat soup, eggs, and cheese.

Typical gout is but an episode in the life of a gouty person; indeed, a man may suffer all his life from gouty manifestations and never have an attack of true gout. As the gouty manifestations are much more important than gout itself, and as the word gout gives no idea of its etiology, I am going to call these manifestations those of protein poisoning. I will illustrate my meaning by the following animal experiment. Horsely and Schiff have shown that if the thyroids of sheep or goats are removed they, being herbivorous animals, are not affected, but if thyroidectomy is performed on dogs they will die. If they are fed on bread and milk or boiled meat, they will live for some time, but if they are fed on roasted meat or meat juice death in convulsions ensues. It seems only logical to assume that the meat contains a poison. Complete thyroidectomy in the human being is fatal to life. I wish, therefore, to advance the following hypotheses:

The animal protein of our food contains a poison, for which the human body has certain defensive agents, which neutralize it and render it harmless. If the protein is given in excess, or is given to an individual who is especially susceptible by having been born into a gouty family, certain manifestations are produced.

In this way the whole question of metabolism may be ignored. When we come to consider the various manifestations of protein poisoning it will be found that most of the diseases not due to infection, namely those in the unknown class, are due to this poison. Although I use the name protein poisoning for lack of a better, it must be borne in mind that the extract of the meat contains more of the poison than the boiled meat and that the poison is probably an extractive of animal protein. My contention is that animal protein contains a soluble poison. From my own experience and that of others in whom manifestations can be produced in a very short time by eating an excess of animal protein, I believe that the poison is directly absorbed and is not a product of intestinal digestion as believed by Combe of Lausanne or a product of metabolism as claimed by Haig of London.

The poison not alone affects every tissue in the body, but can also affect the function of an organ, as, for example, it can cause periodic polyuria, which is a frequent symptom of protein poisoning.

As I seem at first to state dogmatically that certain affections are caused by animal protein, I will explain that in a study of a very large number of cases, over two hundred, I found these manifestations so closely associated with manifestations that can be proved to be due to animal protein in the diet that it seems only logical to assume that they are due to the same cause. In the second place these affections occur only in patients who have a history of other protein poisoning manifestations and in whose family manifestations of protein poisoning are common. In the third place these affections can be very much relieved or cured entirely by the withdrawal from the diet of animal protein.

That the ductless glands should often be affected is not strange, for they are, probably, the chief agents in neutralizing the poison. They are liable to hypertrophy from increased exertion, and if they are called upon for a great excess of secretion, the body itself may suffer from the effects of that oversecretion. Simple goiter, exophthalmic goiter, and the diseases due to hypertrophy and oversecretion of the pituitary body are thus explained. Oversecretion of the adrenals may lead to arteriosclerosis and its results. I have found goiter and exophthalmic goiter very common among those having other manifestations of protein poisoning. The simple hypertrophy of the gland in young women at puberity occurs frequently in gouty families and is some times associated with menorrhagia. The simple goiter of pregnancy is probably explained by the increased work the gland is called upon to perform. Exophthalmic goiter occurs frequently, and less evident signs of hyperthyroidism are very common in patients having other signs of protein poisoning, such as purpura, hay fever, nasal turgescence bronchial asthma, migraine, gouty pains, and the various skin lesions.

Headache is probably the most frequent symptom of protein poisoning; it may take the form of migraine of neuralgia or pain in the insertions of the muscles. Headache that is not due to eyestrain or sinus trouble is usually due to protein poisoning.

There are various neuralgias, myalgias, and pains in the joints which can be experimentally produced in a susceptible subject by taking an excessive amount of animal protein. By a susceptible subject, I mean one who has either consumed a large

amount of animal protein during his own life and so become susceptible, or who has inherited (and this is most always the case) the susceptibility from his ancestors who were also subject to protein poison manifestations.

Periodic turgescence of the nasal mucous membrane is a very common manifestation of protein poisoning; this can also be experimentally produced in a susceptible subject by taking an excessive amount of animal protein. This affection is very important, for it often leads to secondary infection of the sinuses and is the primary cause of sinus trouble. It is often treated by cauterization and removal of the turbinates, the primary cause being overlooked. These patients are subject to hay fever. Hay fever is itself a manifestation of protein poisoning, and occurs only in families with a gouty history, and sufferers from hay fever usually have other manifestations, as for example migraine, purpura, bronchial asthma, or gouty pains. Periodic sore throats which may become chronic, bronchial asthma, and chronic bronchitis are also manifestations of protein poisoning. Susceptible patients are very liable to frequent coryzas. Follicular tonsillitis is very common in patients having protein manifestations; this of course is an infection, yet it is quite probable that, as the germs are always present on the tonsil, the poison eliminated causes an irritation which is followed by secondary infection.

In the digestive tract the most common affection that I have noticed is hyperacidity. Almost all sufferers from protein poison have digestive troubles of which hyperacidity and its accompanying constipation are very frequent. In one case of very obstinate cankers of the mouth of over a year's duration, I found that the cankers disappeared in a very short time with the withdrawal from the diet of all animal protein. This made me think of ulcers in other parts of the digestive tract. Much to my surprise I found that all my patients who had ulcer of the stomach or ulcer of the duodenum had other symptoms of protein poisoning and had also gouty family histories. The irritation caused by the elimination of the poison is very likely the primary cause of ulcer of the stomach. Another common manifestation is periodic intestinal colic. This is often mistaken, especially in children, in whom this manifestation is quite frequent, for appendicitis. Periodic diarrhea without apparent cause is common, this is a condition that is much influenced by atmospheric conditions. Some patients suffer from morning diarrhea which seems to act as a safety valve for their other manifestations. Mucous colitis is another manifestation. In the secretions of mucous colitis eosinophiles are found, as in the secretions of bronchial asthma. Eosinophilia in the blood and in the secretions is a characteristic symptom of protein-poisoning manifestations, especially of the skin and mucous membranes.

There are many protein poisoning manifestations in the skin, such as urticaria, angioneurotic edema, eczema, ichthyosis, and psoriasis. Urticaria frequently follows an excess of protein in the diet and certain individuals seem especially susceptible to special proteins such as fish, white of egg, etc. Angioneurotic edema often occurs in connection with other protein poisoning manifestations. The sydrome that Professor Osler speaks of is an example. Eczema occurs both in the old and young. The children of gouty parents often have eczema which can be cured by the withdrawal of animal protein from the diet.

Ichthyosis is often seen in several members of a family and is hereditary. I have a family in which, besides the ichthyosis that three members have, one has arthritis deformans, two others have periodic attacks of intestinal colic, and one has a goiter. It is well known that the thyroid extract has considerable effect on ichthyosis. Schamburg has shown the effect of the withdrawal of protein from the diet on psoriasis. Acne is an example of a skin affection, when the infection is secondary to the irritation caused by the elimination of the protein poison. Acne is found almost entirely in gouty families and in connection with it one can also find other evidences of protein poisoning. In my own case I found that the acne which I had always had on my back would disappear entirely on my abstaining from animal protein. In a case of exophthalmic goiter which I have treated recently, the patient had a decided gouty history and his face was covered with pimples. Upon withdrawing the protein and giving a suitable eliminative treatment his symptoms of hyperthyroidism as well as his acne disappeared very quickly.

Periodic outbreaks of purpuric spots in women are far more common than are generally supposed and will often be found if looked for. They are in my experience found only in families whose members present other evidences of protein poisoning and are, I believe, an evidence itself of protein poisoning. Hemorrhage from the mucous membranes is a very common manifestation of protein poisoning, for example, nosebleed and menorrhagia. Pupura hæmorrhagica is a syndrome in which several manifestations of protein poisoning are combined, such as intestinal colic, hemorrhage from mucous membranes, hemorrhage into the skin, and sometimes fever. I have one very interesting case of pupura hæmorrhagica of the intermittent type. The patient is subject to gouty pains and headache, and is a sufferer from hay fever. One brother has gout, another bronchial asthma, her daughter suffers from nasal turgescence, has a goiter and is afflicted with acne. This patient has also with her purpuric attacks, bleeding from the bladder and rectum, renal and abdominal colic, and nasal turgescence, and the attacks are often followed by furunculosis.

In the joints we may have gouty pains, inflammation, or chronic conditions such as Heberden's nodes and arthritis deformans. In the muscles are the various myalgias, lumbago, stiff neck, etc. In the nerves, supraorbital neuralgia is very common, also sciatica and other forms of neuritis. These can be said to be due to protein poisoning only when there are other manifestations such as nasal turgescence, asthma, enlargement of the thyroid; but if careful examination is made this will almost always be found to be the case.

In making a diagnosis of protein poisoning the family history is of extreme importance, for perhaps the most important and most interesting characteristic of protein poisoning is the inherited susceptibility. I can show among my cases, four and five generations of inherited susceptibility. For instance, in one family there were five generations of purpura (all in females) several of the children in the fifth generation had goiters, and one had an exophthalmic goiter; many in this family were subject to migraine and various sorts of gouty pains in muscles, nerves, and joints.

The multiplicity of the manifestations in the same individual is characteristic. A patient will have Heberden's nodes in the fingers, will be subject to periodic turgescence of the nasal mucous membrane, have purpuric spots, hyperacidity, and be subject to neuritis. Another patient will have a slight enlargement of the thyroid, have attacks of bronchial asthma, migraine and mucous colitis, besides various myalgias.

The variability of the symptoms in parent and child is characteristic. A father may have gouty pains and chronic bronchitis with a tendency to asthma, and one child have very bad acne, another bronchial asthma, and another a goiter, all the children having other manifestations in addition. The grandchildren will, when young, be subject to acidosis with symptoms in either the respiratory or digestive tract as well as in the skin.

The periodicity of the attacks is characteristic, as for example migraine, bronchial asthma, periodic nasal turgescence and sore throat.

The cessation of one set of symptoms with the onset of another is most peculiar. A man will have a violent urticaria which will stop with the onset of asthma. When the asthma stops the urticaria will commence again. A patient having been operated on for floating flidney which was really renal colic will be cured of her hyperacidity also, but will be troubled with nasal turgescence after being treated for so-called sinus trouble, that will stop and she will suffer from bronchial asthma, that will get better, and then she will have lumbago and intercostal neuralgia which she and perhaps her physician calls pleurisy. I have such a case that was treated by fourteen different physicians before I made a diagnosis of protein poisoning. She was a very heavy meat eater. She had been treated for tuberculosis, floating kidney, sinus trouble, pleurisy, etc.

Atmospheric conditions and climate have considerable influence on the manifestations of protein poisoning. Damp weather will often bring on an attack of migraine, bronchial asthma, pains in the joints, nerves, or muscles, or an attack of mucous colitis. Some of the conditions are wonderfully improved by a change of climate, for example asthma or chronic bronchitis.

The eosinophilis are often much increased in certain lesions of the skin and mucous membrane in poisoning by animal portein, for example urticaria and bronchial asthma. In mucous colitis and bronchial asthma the eosinophilis are found in excess in the secretions. Acetone is often present during attacks and is present in excess in a subject even when free from attacks.

The acidosis in children is really a protein poisoning, and it may show itself in a great variety of symptoms. In children considerable fever is often present when the respiratory mucous membrane or the mucous membrane of the digestive tract is involved. Sore throats and intestinal colic are very common. The intestinal colic is often mistaken for appendicitis.

I have one patient who has had three major operations for severe abdominal pain which we know now was due to protein poisoning, her kidney was found normal, her gall-bladder also, and at another time her appendix was removed though normal. She had other gouty manifestations, she was of a gouty family; she had a high percentage of eosinophiles during attacks and acetone in the urine.

In some cases the condition is mistaken for tuberculosis. I will cite a few cases in my practice.

Case I.—About six years ago I examined a young woman who had a cough, some rales, and a persistent evening rise of temperature. There was an old tuberculous lesion at one apex, and signs of an old pleurisy. At the time I examined the blood every day for a week and found that the percentage of eosinophiles was constantly very high, over fifteen per cent., which I thought at the time might be due to an intestinal parasite. I made a diagnosis of active tuberculosis and the woman passed several years in various sanitoriums. There never was much sputum, and no bacilli were ever found. Although the *x*-ray showed the old lesions, no one was ever able to locate the active lesion, the only symptom of which was the persistent slight temperature. Recently I was called to see her and found her suffering from an active nasal turgescence, there was acetone in the urine, and eosinophiles were again increased. I then remembered that I had once treated her for goiter. Then it all flashed upon me that she had been suffering all the time with protein poisoning. She had a well marked gouty family history.

Case II.—My assistant at the Children's Free Hospital dispensary wished me to look at a case in which he had made a provisional diagnosis of acute miliary tuberculosis. I noticed on examination that the breathing was labored and that the child had a goiter. There were rales all over the chest. The mother and three other children, who were present, had goiters, the mother had gouty fingers and eczema on her hands, one child had an active urticaria. The mother said she fed the children principally on meat, meat soup, and eggs. The patient was suffering from bronchitis with asthma, and was a victim of protein poison.

We have found on reconsidering our diagnosis at the South Side Dispensary for Tuberculosis that there are probably dozens of children in whom we have made a diagnosis of tuberculosis, because they had a persistant temperature who really had protein poisoning. This is a typical history of a boy in which a diagnosis of tuberculosis had been made on account of occasional rales and a persistant temperature; he is robust and seems perfectly well now.

Case III.—Edward P., age eight years, had eczema when an infant, the eczema will appear now at times; he gives a history of attacks of shortness of breath. The present attack has lasted eight weeks, he is now suffering from polyuria, and has a persistent rise in temperature. The mother of the patient has gouty pains in he arms, especially in damp weather, she has acid dyspepsia and frequent outbreaks of ache on her back. She is troubled with a planter wart. Her father had rheumatism and asthma. One sister has gouty pains and frequent headaches and suffers from hay fever.

I have pointed out how animal protein poisoning may resemble tuberculosis. It also in some cases produces symptoms that resemble typhoid fever or meningitis.

Case IV.—I have a case now under observation in which a diagnosis of typhoid was at first made. There has been a continued fever with daily remissions for over six weeks. Repeated blood examinations fail to reveal the typhoid bacillus or give a Widal reaction. Eosinophiles could be found in the blood, as is not the case in typhoid. Acetone was present in excess at first, but with the withdrawal of all animal protein and the giving of sodium bicarbonate that has disappeared. The patient looks perfectly well and feels so, except that she has a fever which looks as if it would continue for some time.

Case V.—We have a case at the Milwaukee Children's Hospital of a boy eight years of age. He had convulsions and a temperature of 105 deg. on entrance with the head symptoms of meningitis. His breath had a fruity odor and acetone was in excess in his urine. Repeated lumbar puncture showed only a clean fluid and his reflexes were normal. There was a considerable leucocytosis. After about six weeks of fever he completely recovered.

I believe many a case of bilious fever is due to

protein poisoning and many a case of recovery from meningitis is really a recovery from protein poisoning.

There are often nervous symptoms connected with protein poisoning. Periodic fits of nervous depression or the blues are very common. One also meets with real neurasthenia which will clear up remarkably with a proper regulation of the diet and eliminative treatment.

I have by no means exhausted the number of protein poisoning manifestations. Probably the whole of the lithemic diathesis of Bouchard should be included as nephritis, the uremias and eclampsias arteriosclerosis, gallstones, renal colic, etc.

Diabetes is very common in the family history of protein poison manifestation. Indeed, as pointed out by many authors, there is a distinct relation between gout and diabetes.

It is possible that the defensive and metabolic agents are so occupied with the protein poison that there comes a time when their ability properly to metabolize the carbohydrates fails.

It is quite possible that protein poisoning has to do with the formation of tumors. I have found fibroids in women and enlarged prostates in men very common, and one can always find in those conditions other manifestations of protein poisoning.

The most interesting condition I have noticed is the history of warts. Of course warts are very common, but those afflicted with plantar warts consult a physician on account of the discomfort.

I have yet to find a case of plantar warts in which there was not some other manifestation of protein poisoning. This leads one to think of carcinoma. According to the French school, carcinoma is usually if not always found in gouty families. A line of research with the idea of protein poisoning being a factor in the cause of cancer should certainly be instituted. Of the cases of cancer of my knowledge, all had some manifestation of protein poisoning.

Although the diagnosis is very easy when the manifestations are borne in mind there is probably no diagnosis so often overlooked. Turbinates are removed, good teeth extracted, and abdominal operations performed when the trouble is simply a manifestation of protein poisoning. I could quote dozens of such cases. If a careful questioning of the patient shows he is subject to hay fever, headache, or neuritis one's suspicions should be aroused. Another patient may have a goiter, purpuric spots, be subject to nosebleed, polyuria, etc.

Another may have acne, warts, hyperacidity, and be subject to muscular rheumatism. Another may have bronchial asthma, periodic asthma, periodic intestinal or renal colic. In all these cases a careful examination of the family history will confirm the diagnosis.

The most important cases are those in which a differential diagnosis must be made between protein poisoning and tuberculosis, typhoid fever, and meningitis, but usually a diagnosis can be made by the presence of acetone and eosinophilia and the absence of the cardinal symptoms of the more serious diseases.

As the manifestations are so various, a consideration of the treatment in detail is out of the question, but certainly no treatment is of much avail without the withdrawal from the diet of meat, meat soup, eggs, and cheese for a time at least.

That considerable improvement in protein poisoning follows the withdrawal of the carbohydrates is probably due to the fact that the defensive and metabolic agents are thereby given more opportunity to dispose of the real offending agent which is the protein.

An eliminative treatment of Carlsbad salts in the morning and acetyl salicylate three times a day is indicated. Bicarbonate of soda and an addition to the diet of plenty of fruit are useful therapeutic measures. I have found in certain cases, especially in neuritis, good results from injections of cacodylate of soda.

The proper administration of the animal extracts is especially useful in purpura, in hemorrhage, and in affections of the ductless glands; also in affections of the respiratory mucous membrane and in other protein poisoning manifestations. Atmospheric conditions (which influence the elimination through the skin and respiratory mucous membrane) have such a strong influence that a change of climate is sometimes of great benefit.

On the whole the treatment is very satisfactory and it is surprising to see how many patients, who have all the sources of focal infection removed without benefit, except the temporary relief due to postoperative starvation, become free from their complaints when animal protein is withdrawn and suitable eliminative treatment advised.

It is unnecessary for me to quote further from the large number of cases I have collected, for I am sure any physician will find dozens of cases in his own practice which will support my contention that animal protein is the cause of almost all disease not due to infection and that these diseases are merely manifestations of damage done to the various tissues of the body through the inability of the natural defenses of the body, of which the ductless glands are among the principal ones, to neutralize and render harmless a poison which is in animal protein.

SOME CLINICAL ASPECTS OF RADIUM THERAPY.*

By WALTER B. CHASE, M.D., F.A.C.S.,

BROOKLYN, NEW YORK,

SURGEON BETHANY DEACONESSES HOSPITAL, CONSULTING GYNECOLOGIST LONG ISLAND COLLEGE HOSPITAL, CONSULTING SURGEON RADIUM SANATORIUM, NEW YORK CITY.

For many years my practice has been, and still is, to operate on all operable large malignant growths, but want of confidence in the ability of myself and more skillful operators to prevent frequent recurrence, has convinced me that operative surgery has about reached the limits of effectiveness, and that perforce we must look to some other supplemental remedy. For ten years it has been my custom to make use of postoperative prophylactic radiation.

As preliminary, reference is made to a few fundamental propositions:

(1) In its incipency cancer is always a single local lesion. (2) Every case of cancer has a developmental period, when early cure is possible, save for anatomical reasons, or coincidental disease. (3) Cure of cancer depends upon removal or destruction of all malignant cells. (4) There are three principal features in the practical application of radium, viz., the amount of radium used, the time of its application, and the tissue resistance of the individual patient. This gives emphasis, that the law of

*Read before the Medical Association of the Greater City of New York, June 5, 1916, at St. George, Staten Island.

radium therapy must be studied in every individual case. (5) The resisting powers of normal structures is much greater than that of tumor growths, and affords a conservative margin of safety, a most important clinical factor. (6) It should also be remembered the younger the patient the more grave the malignancy and vice versa.

The results of radium treatment are palliative and curative. The palliative influence of radium is fourfold: (1) analgesic; (2) inhibition or arrest of malignant or benign growths in varying degrees and for varying periods of time; (3) its property of diminishing or destroying offensive odors in local ulceration, malignant or non-malignant; (4) its efficacy as a hemostatic in uterine hemorrhage. In these several applications of its therapeutic influence are opened fields of knowledge little known and less appreciated, often offering a boon to the discouraged—the only barrier against utter hopelessness.

Postoperative Prophylactic Radiation. — When operative surgery with its unnumbered victories in the cure of cancer, with its perfected technique, guided by the tact and skill of the accomplished operator, does its best in the hope this will effect a cure, the period of suspense and anxiety remains until three to eight years have passed if the patient survives so long. This anxious solicitude arises from fear that areas of malignant cells, of unknown and unknowable location, have not been removed by the scalpel, and may remain as a ménace of renewed lawless proliferation, the essential and pathognomonic feature of malignancy. It is this persistency of recurrence which leads an increasing number of operators to resort to postoperative radiation. This has been my practice for ten or twelve years until I have come to believe the last prohibitive and possibly curative step has not been taken until radium has been used. Briefly, but in no exhaustive way, I shall quote from authorities who resort to radiation in postoperative cases. It is here that surgery and radium find ample opportunity of reciprocity, without infringing on the rights of either, a precedure which offers ample encouragement for general adoption.

Miller[1] says prophylactic raying after operation is now fairly well established on a rational basis. In six utterly hopeless cases, from a surgical standpoint, of recurrent carcinoma, following hysterectomy, four yielded to radium treatment, but final results cannot yet be known. Two other cases were only temporarily benefited. One point in favor of radium which should not be overlooked in the final analysis is that the present statistics will be based on material that had passed beyond surgical relief before radium is used.

Nahmmacher[2] deduces that operable tumors must be operated upon unless the operation is refused, and the operation must be followed by prophylactic radium treatment. Inoperable tumors must be rayed immediately.

Foveau de Courmelles[3] states that radium and *x*-ray should not be regarded as antagonistic to surgery, but as accessory means. All operations for cancer should be followed by prophylactic radium.

Schmitz[4] says that radium therapy is indicated (1) In inoperable cancers of the uterus, vulva, and vagina; (2) in operable cases where operation is refused or is otherwise impossible. The results of radium therapy in the London Radium Institute,[5] presided over by men of worldwide reputation (Teeves, Brunton, Ramsey, French, Tate, Pierce, Pinch, and others), are worthy of particular notice; more so as it is the rule of this institute to use radium only in inoperable cases, with a few exceptions. In this annual report they say: "During the year 1914 the number of patients was 841. There were no selected cases, and radium was never used but in inoperable cases, excepting those who refused operation, or where radium was used as a last resort. Since the opening of the institute in 1911, numerous patients who have undergone operations for malignant diseases have received postoperative prophylactic radiation. It would be exceedingly difficult, if not impossible, to make any statement as to the precise value of radium treatment in preventing or minimizing the danger of recurrence, but as the majority of these cases have suffered from severe and extensive and rapid progressive malignant disease, and the operators had expressed grave doubts as to the possibility of remaining free from the disease for more than a few months, the relatively slight proportion of recurrences so far recorded (19 per cent. does much to justify routine postoperative radiation. It should prove of special service in those malignant growths in which it is found impossible to operate well beyond the appreciable area of the disease."

If since August, 1911, the time this Institute was opened, such results have followed in cases regarded as almost hopeless, the operator who carries his effort to the extreme limit of surgical possibility, can feel one other opportunity remains of palliation, if not of cure, sufficient to keep the fire of hope burning in the most unfortunate of mortals. What operator for the most favorable cases of malignant growths can produce reliable statistics so favorable —only 19 per cent. of recurrences—in cases almost hopeless, for a similar period of time? It should require no argument to establish the efficacy of radium thus applied. It is of supreme importance that postoperative radiation be applied soon, when granulations are well established, and that one should not wait for recurrence, when the chances of control are greatly minimized. When it is remembered that the traumatism of operation is a potent factor in rekindling the fires of malignancy, precious time will not be lost in waiting for such developments.

It is encouraging to note the surgical world is awakening to the value of and necessity for postoperative prophylactic radiation. This is evidenced by a growing desire among operators in this country for its early application. It is already appreciated and used in the great European centers. It is particularly gratifying it is being used for such a purpose in the great clinic at Rochester, Minn. These facts give impetus to the prospect that such a procedure may in the near future become an established routine surgical necessity. The period of time intervening between radical operation for cancer and postoperative prophylactic radiation—often months or years—is a serious barrier to the best results radium offers. At this time a patient under my care who was operated on two years since by a surgeon of distinguished ability, dosages of 600 mgm. of radium offers faint hope of benefit.

A common procedure—that of taking a section of cancer growth for diagnosis, independent of preparation for immediate laboratory diagnosis at the time of operation, is a step fraught with grave risk to the patient, by stimulating, as just referred to a more rapid development. Make your Wassermann, differentiate rational and physical signs, but rather

trust to clinical diagnosis than risk such a procedure. Exceptions to this rule are found in making sections for deep-seated growths, the diagnosis of which could not otherwise be formulated. The time, the period of its use, are matters which demand experience obtained only by close observation and seasoned judgment.

Preoperative radiation has a place in cancer therapy. In cases where the surgeon is in doubt as regards removal of large growths, on account of tumefaction and pronounced fixation, it is found the gamma rays will promote absorption of effusion, often non-malignant, by its decongestive influence, diminishing infiltration, and glandular enlargement, whereby mobility is increased, and the size of the tumor and its relations determined.

Schmitz[4] says, "In fact, an inoperable uterine cancer may be made operable within about three or four weeks by the use of 3000 or 4000 mgm. hours of radium. The objective changes are restoration to its former shape and disappearance of the infiltration of the perimetrium and recurrence of former mobility—while the subjective changes are a cessation of hemorrhage and cachexia, and improvement in the general condition of the patient." It requires no prescience to appreciate how greatly improved the chances of the patient are—say, in mammary cancer—when operation is preceded by absorption or destruction of structures, which were barriers to accurate dissection and primary union. It may, and often does, determine the great question whether to operate or otherwise.

The following cases illustrate the value of radium in relieving pain and arresting hemorrhage:

Case I.—H. W. C., male, age 56, came under my care January, 1914, suffering from inoperable cancer of the throat and tongue. He was weak, mildly cachectic, suffering nagging pains which yielded to radium treatment, amounting in all to 700 mgm. hours up to June 30. At this time the pain was so abated all opiates were discontinued, and he was free from pain up to Aug. 30, the time of his death.

Case II.—Mrs. W., age 44, married, multipara, a patient of Dr. Stevens, of this city. Seen October 30, 1915, suffering from cervical cancer, with metastasis, too late for radical operation. Two thermocautery operations were done during the continuation of the illness to lessen the areas of carcinomatous growth on the cervix and vagina, with marked benefit. After the second thermocautery operation both hemorrhage and odor were corrected by the occasional use of radium. During the earlier three months of treatment, radium was applied at intervals aggregating 700 mgm. hours. During the last three months and up to the time of her death, no anodynes were required.

Case III.[5]—Mrs. K., of Jersey City, multipara, aged 32, first seen September 1, 1914. Advanced inoperable carcinoma of entire uterus, suffering hemorrhage, cachexia, and great exhaustion, taking opiates. Commencing September, 1914, radium was used twice a week. In less than a month pain was almost absent, hemorrhage controlled, appetite and strength much increased. From this time on until three weeks before her death in January, 1915, she was almost without pain. The potency of radium as a hemostatic and as an analgesic was well illustrated in this case.

Case IV.[5]—Mrs. L., aged 70, widow, mother of four children. Came under my care February, 1911, with cervical cancer of the cauliflower variety. She was weak, cachectic, with a prospect of living six or eight months. She had three thermocautery operations, each followed by the use of radium; after the second operation almost complete healing took place. Recurrence followed and radium was again used with partial healing. She remained free from hemorrhage and pain, though in declining health until January, 1915, the time of her death. It is quite safe to affirm that three years of comfortable existence were afforded to her by thermocautery operations and radium.

Case V.—Mrs. A., aged 57. Menopause about seven years previous. Some eight months past, after a fall, striking on upper portion of sacrum with contusion of the abdominal wall over the right ovary, her physician feared malignancy. Her health failed and ordinary activities were almost suspended on account of localized pain in the lower right segment of the pelvic cavity; the right ovary was painful and tender, and there was pain in the region of distribution of the sacral nerve, attended with occasional loss of blood. Four applications of radium were made in August, 1915, in vagina and crossfire from lower abdominal wall. Pain abated, the uterine hemorrhage was arrested, and she recovered average health.

A physician of this city reported to me recently an advanced case of cancer of the stomach and pancreas in a woman aged seventy, where pain was only mitigated by opiates. Immediately following an intravenous injection of 100 micrograms of radium salt, there was complete relief of pain up to the time of her death, six weeks later. This case, with others, gives confidence in the belief that this newer method will prove valuable. If radium possessed only the single property of palliation it would justify the enormous expense incident to its production. It is stated as a general procedure that uterine cancer, cervical or corporeal, without metastasis should be removed by panhysterectomy, except when coincident conditions make it impracticable.

Uterine Hemorrhage.—Perhaps no field of radium therapy at the present moment is attracting so much attention as its influence in uterine hemorrhage, of diverse pathogenesis. This applicability embraces the hemorrhage due to uterine fibroma, chronic polypoid endometritis, hemorrhagia metropathica (with slight findings), in the bleeding of young girls, and to degenerative and vascular changes at the menopause. Kelley[8] recommends thorough dilatation and curettage with applications of radium made to the uterine cavity. These results may be augumented by cross-fire of radium in the vagina, rectum, and over the abdominal wall. Very serious bleeding occurs in uteri so small as to make intrauterine application of radium impracticable or impossible. Here radium cross-fire affords opportunity for ample gamma-ray influence.

Three months since a woman of forty-eight—at the menopause—was suffering from metrorrhagia due to diffuse uterine fibroma. The size of the uterus, which was symmetrically enlarged, was that of two and one-half months' pregnancy. Intrauterine use of radium in a single dose of 800 mgm. hours was administered. The uterus diminished 25 to 30 per cent. in size, and the hemorrhage was to a large degree controlled so that she may not require further treatment.

Case VI.—Mrs. M., aged 61, weight 235 pounds, apparently in robust health. Passed the menopause eight years since. For five years has flowed occasionally following unusual exercise. First seen September 15, 1915, with her physician and another consultant. There was an edematous condition of the cervix and uterine body and portions of the vagina; depth of the uterine cavity three inches. Suspicious of corporeal malignancy, curettage for diagnostic purposes was advised and declined. Between September 15 and October 13, three hundred and fifty-two mgm. hours of radium were applied with cross-fire at intervals. No recurrence of hemorrhage until December 18, when it became profuse. Curettage was done and radium applied to the uterine cavity for five hours. Three times radium was used up to March 2 for slight hemorrhage. On May 5, over two months from last use, a more active hemorrhage appeared and 800 mgm. hours of radium were applied in the uterine cavity, since which date there has been no hemorrhage; health good and she goes about as usual. While recovery is not anticipated, there is reason to hope her life may be considerably prolonged. Her age, the low type of malignancy, her susceptibility to radium, as already demonstrated, combine to strengthen the possibility.

Case VII.[9]—Mrs. J. M., aged 30. Compiled from the official reports of my work during July, August, and September, 1915, at the Norwegian Hospital, in the service of Drs. Delatour, Skelton, and Graham. This patient has serious metrorrhagia; she is very pale, complains of weakness, headache, and backache. Admitted to Norwegian Hospital July 20, 1915. History shows she has been bleeding for one year and four months, the flow being practically constant. On admission she was markedly exsanguinated, heart sounds weak, respiration 25, pulse 80 to 90, hemoglobin 40 per cent. Pelvic examination revealed a moderately prolapsed uterus and first-degree retroversion. Diagnosis polypoid endometritis. July 21 to 24, serious uterine hemorrhage, so marked as to require vaginal packing to control it. July 25 packing removed, and Dr. Chase introduced 25 mgms. of radium into the uterine canal, which was removed after thirty-three minutes. July 26, considerable bloody discharge. July 31, enough discharge to cause spotting. August 1 and 2, no bleeding. August 22, slight discharge. August 23, bleeding stopped. August 24, discharged, to return for observation by request. General condition improved, hemoglobin 70 per cent. The patient began to feel better and increased in strength from the very date she was given radium. Up to October 7 she had not returned.

The extreme weakness of this patient forbade any heroic measures, and even curettage (much more hysterectomy) was contraindicated. At the time the radium was used she passed into a condition of syncope, and the extreme weakness forbade any effort at cervical dilatation. Recent inquiry early in May gives the belief that the woman is in comfortable health and is employed as a janitress.

Case VIII.—Official report of radium treatment at the Methodist Hospital, service of Drs. Spence and Graham. Mrs. E. S., aged 47, multipara. Complains of bleeding from vagina; health has always been excellent. Menstrual history shows she was regular until June, 1914; duration of flow five to six days; no dysmenorrhea. Did not menstruate from June, 1914, until March, 1915; was not pregnant. This period was one of normal duration. Did not menstruate again until September, 1915, and continued to flow until October 30. Began latter part of September with scant bloody discharge, which later became profuse, with no membranes. Since she came to the hospital she has had very little bleeding, but she bled some November 5. The next day radium treatment was applied by Dr. Chase, and she has had no bleeding since. The cervix was found to be apparently normal but the uterus was very small, about the size of an English walnut. Radium was used but once and then by cross-fire in the vagina. Information received June last confirms the belief she is in fairly good health.

Case IX.—*Bone Carcinoma.*—Miss L., of Buffalo, aged 20, was seen by me April, 1915. She had been an invalid for seven years from involvement of the left hip and later the left ilium. Her first physician regarded the case as rheumatism, and treated it accordingly. Later another physician diagnosticated it tuberculous, and she wore plaster casts at the hip without relief. At this juncture an *x*-ray picture was taken showing enlargement of the upper portion of the femur and ilium. A portion of bone was removed from the great troachanter and the laboratory diagnosis established the presence of carcinoma. She entered my service at Bethany Deaconess Hospital in this city May 30, 1915, and remained until July. During this period radium was applied twenty-five times at varying intervals, amounting in the aggregate to 2650 mgm. hours. Once it was buried behind the trochanter major and once over the ilium above Poupart's ligament for a period of twelve hours. Her health was improved and she returned to her home. There has been some fluctuation in her condition since that period, but under date of May 30, 1916, she reports herself very greatly improved. Is able to go down stairs, sit in hammock, and quite satisfied to remain as well as she is. This patient should have more radium.

Case X.[10]—*Sarcoma.*—Mr. H., aged 52, came under my care at Trinity Hospital December, 1914, for radium treatment, after removal by Dr. Campbell of a melanotic sarcoma the size of a hickory nut at middle third dorsal aspect of right arm, which refused to heal. Radium was applied three times, healing promptly followed, and at this date there is no recurrence.

Briefly I refer to two other cases of sarcoma occurring in the joint experience of Dr. Bissell and myself in St. Vincent's Hospital two years since. One patient, C. V.,[8] in whom hip and thigh were extensively involved from violent traumatism, became so much worse that death seemed imminent, but recovered after three applications of radium buried in the thigh, so as to resume laborious work for a year or eighteen months. This case has attracted much notice from various sources, and is mentioned by Coley in his article on Sarcoma of Long Bones in the *Annals of Surgery*, 1914. He has suffered relapse—has drifted about to different hospitals. At present he is recovering from a radium burn, but apparently will be able to resume work when healed. The other case,[6] one of recurrent sarcoma over the scapula, healed promptly. The patient removed West, and has not been heard from since.

Epithelioma is more easily mastered than most forms of cancer, particularly the basal cell variety. If the ulcer occurs near or after middle life, particularly if it is of the cutaneous variety, and not of too long standing, or not consisting of old and well differentiated cells occurring on mucous surfaces, they are more refractory, but with wise management cases are recoverable. The use of needles containing radium plunged into the tumor, whether in the throat, tongue, or tonsils, and in many external large growths, has brought about improvement. This form of using radium is only in its infancy, but promises advantages over other methods, in properly selected cases, and we are constantly demonstrating its utility in the Radium Sanatorium of New York City.

Mammary epithelioma,[5] if seen and attacked before metastasis, yields results often satisfactory. I reported such a case in a woman aged 80 having cancer of the right breast, who was altogether relieved in 1914, and remained in perfect health since.

I have experienced great satisfaction in observing recently the results of radium in large cutaenous epitheliomata of the face disappearing under one, two, or three treatments. During the past year a physician of this city was treated by me for epithelioma of the hand. Healing was complete after three applications. Another case, an Italian fish monger, had epithelioma of the face, so offensive that patrons refused to deal with him. It disappeared entirely after three radiations. A physician of this city[6] suffered from pronounced hyperkeratosis of the hand due to *x*-ray burns, a tumor the size of a chestnut forming between the second and middle fingers on the dorsal aspect. There was no healing after operation, but recovery followed almost without scar after three applications of radium. This case illustrates, paradoxical though it may appear, what is amply confirmed by authoritative observation, that *x*-ray cancer is curable by radium. Tousey[11] gives personal experience to the usefulness of radium in combating hyperkeratosis resulting from *x*-ray exposure.

The field of radium therapy is so broad that only points can be considered here and there. My experience in treating inoperable cancer of the rectum is not altogether discouraging, particularly if it is seen early, and is of the annular variety. When radium does not effect a temporary cure, it often inhibits growth and diminishes pain. About two years since,[7] a woman, aged 50, came under my care after operation for carcinomatous degeneration of a rectal polypus. Six applications of radium of fifty to one hundred mgms. each were made within a

month. The growth was two and one-half inches from the anus and involved three-fourths of the circumference of the gut and was of the annular variety. She remains in good health. Last August another similar case, not yet reported, appeared in a woman 45, who, at the time, was suffering from what was feared to be malignant ulceration of the stomach; she was confined to her bed and greatly exhausted. Radium was used as in the former case. Amelioration of the general condition followed and with it relief of the gastric symptoms. At the end of a month the growth had disappeared and with it other coexisting troubles. Recently she is in good health.

Another inoperable case of rectal cancer[4] was relieved and life prolonged which is worthy of mention.

The possibility of intravenous injections of radium salt and the use of radium water holding in solution radium salt, or emanation, in chronic rheumatoid arthritis, arthritis deformans, chronic rheumatism, arterio-sclerosis with high blood pressure, with or without renal or hepatic complication, and neuritis with faulty metabolism and inadequate excretion, might occupy this whole evening. Perhaps in the whole field of radium therapy the results are nowhere more surprising and startling than in this class of cases. Coincident with the use of radium in this manner are evidenced an increase in red blood corpuscles and hemoglobin, and augmentation of nervous and muscular vigor, in many cases wholly outside of ordinary experience. Few unprejudiced observers can reach any other conclusions. Evidence is not wanting[12] that it is possible to reduce the blood pressure not only temporarily but in a proportion of cases permanently.

It may be noted[10] that a practical field for the use of radium is found in tuberculous glands in which the cosmetic results are most satisfactory. The same results are frequently seen in goiter.[11]

The demand for larger practical knowledge of radium and its uses, forces itself on our consideration, as the subject expands in breadth and interest. Among the multiple questions propounded, not yet elucidated, is the problem how to apply radium so as to secure the maximum of good results. Up to this time the matter of screening without large and cumbersome covers has been an embarrassment in securing ideal results. Apparently this problem is now receiving a satisfactory solution in the Radium Sanatorium in New York City. Here we use hollow needles, holding smaller or larger quantities of radium effectively screened which can be plunged directly into benign and malignant growths, large or small. Particularly is this applicable in applying radium to the tongue, tonsils, and pharynx, owing to difficulty experienced in keeping the applicators in proper position. In large growths, needles of varying length can be introduced at regular distances and varying depths, so as to maintain an effective cross-fire, not only, but to reach large areas at greater depths thereby affording adequate gamma radiation.

When massive quantities of radium are applied externally for deep penetration of the liver, spleen, pancreas, and other intraperitoneal viscera, this method has an effectiveness hitherto impossible.

In the present state of our knowledge the outlook for the mastery of cancer by one method has not been realized. The surgeon with his scalpel, the use of radium and *x*-ray, the application of cold and heat, and the destruction of tissue by chemical agents are all curative in their own sphere, but leave more to be desired than has been accomplished.

I have in this paper shown how one or more of these agents could follow each other with advantage and effectively, but until hearty co-operation and reciprocity are established, the highest ideals now possible in the treatment of cancer will lack accomplishment. For such co-operation my appeal is made to this body of influential and distinguished members, and to the entire medical profession, until such time as research work, ably and persistently carried forward, reveals a positive antidote.

ECLAMPSIA, A PREVENTABLE DISEASE.*

BY JOHN W. WINSTON, M.D.,

NORFOLK, VA.

IN order for this to be a preventable disease there must be hearty cooperation between physician and patient. It is the duty of a pregnant woman to herself, as soon as she becomes pregnant, to present herself to her physician for a thorough examination; and it is the duty of the obstetrician to his patient to make himself thoroughly acquainted with her physical condition.

The time has passed when a woman, because of modesty, should take for granted that she can manage her own affairs when pregnant, until the time for labor, and the obstetrician is grossly unfair who consoles his patient with the idea that everything will go along smoothly without first knowing her physical condition.

The physician who does good obstetrics to-day must have recourse to the blood-pressure test, as it ranks ahead of uranalysis, and it is on this point, which is often neglected, that I wish mostly to dwell.

Von Basch, in 1881, was the first to use the sphygmomanometer for the clinical study of blood pressure. Flint, in 1886; Delafield, in 1891; Stengel, in 1899.

The first reports of observations on human blood pressure were made in 1903, by Richard C. Cabot, and a more detailed report in 1904. Janeway first contributed to the literature of the subject in 1906. The October, 1915, number of the *Johns Hopkins Hospital Bulletin* contains an up-to-date contribution to the subject by Janeway.

With the stethoscope over the brachial artery, the pressure is increased around the arm until all sound stops, when it is gradually reduced until a sharp tap is first heard, which marks approximately the

*Read before the Norfolk County Medical Society, April 24, 1916.

systolic pressure. The pressure is still further lowered until all sound disappears, when it is again gradually raised to the point where the first tap is audible, and this marks approximately the diastolic pressure. The difference between the two is called the pulse pressure.

Diastolic pressure is more constant than systolic, and, as it measures the peripheral resistance, it would seem to be a more accurate index of either high or low tension.

In high arterial tension, a large pulse pressure occurs which seems to be compensatory, while a low pulse pressure is the sign of a failing heart. A pulse pressure below 30 mm. is low, and one above 50 mm. is high.

It is important then to know all three pressures in a beginning pregnancy. As the distance between the systolic and diastolic widens as the pressure goes up, it would seem safer to trust to the systolic in pregnancy until more observations are made with the diastolic.

The systolic pressure ascertained by palpation is from 5 to 10 mm. lower than that by auscultation, and this is the method most used to find it, and the one referred to in this paper.

Early toxemia is indicated by a rise in blood pressure, and any departure from a normal metabolism is shown, and shown before any physical sign or any noticeable change in the urine.

Blood pressure should be taken from the first, in the pregnant woman, so as to know the pressure normal to the individual and to be able to watch any change.

As soon as pregnancy is established the urine should be examined and the blood pressure taken, and continued every two weeks until the last month and a half, and then at least once a week. A record should be kept, and signs of danger should shorten the intervals of examination.

John C. Hirst, in a report of 100 cases, found the average systolic pressure 118 mm. up to 7½ months, after which there was normally a rise of 8 or 10 points. According to H. C. Baily, individual readings vary to the extent of 30 mm. without having any significance. Blood pressure during labor, in normal cases, averages a rise to 140 and 150 mm.

John C. Hirst says that a high and constantly rising blood pressure always precedes albuminuria and all the constitutional signs of an impending eclamptic attack.

Baily says that convulsions may occur and the blood pressure be no higher than 155 mm. Hirst says that 192 mm. is the highest blood pressure he ever saw without eclampsia, and that the highest in eclampsia was 320 mm. Both Hirst and Baily say that blood pressure in the early toxemias (persistent vomiting) is often low.

As far as it is possible to lay down any definite rule, we may say that a pressure below 125 mm. can be disregarded; a pressure from 125 to 150 mm. needs careful watching and moderate treatment; a pressure of 150 mm. which was at the beginning 100 mm. is more serious than one that was 130 mm. at the start. A pressure above 150 mm. needs, usually, active eliminative treatment, and if it persists in climbing higher it will, in all probability, require the induction of premature labor.

F. C. Irving reports that the blood pressure in 5,000 cases ranged from 80 to 225 mm.; 400 of this series were never below 100 mm. or above 130 mm. F. S. Newell found from 100 to 130 mm. a normal range in his cases. Haussling puts the average from 100 mm. to 135 mm. Irving says a lower pressure than 100 mm. occurred in 9 per cent. of his cases, and that it has little significance, but is an individual peculiarity. All of the cases he classes as toxemia had, at some time, both albumin and elevated blood pressure, and he applies the term toxemia to those cases having at some time both manifestations, with the addition of one or more of the following signs or symptoms: Headache, disturbance of vision, persistent vomiting, epigastric pain, antepartum bleeding, and edema.

The specific gravity of the urine varies with the intake of water, but, if studied, is of the utmost importance, a persistently low reading in a pregnant woman being a dangerous sign. Irving found albuminuria and toxemia most frequently in women under 20, and high pressure in them a more serious sign than later in life. In elderly women, a high pressure was more common, with seemingly less importance as an evidence of toxemia. Between 20 and 30, he found that elevated blood pressure and toxemia were least common, making this decade the safest for child-bearing.

Albuminuria occurs oftener than elevated pressure, but is at times of no significance. Whenever albumin is found the urine should be centrifuged, and examined under the microscope to determine the cause.

Irving also finds elevated blood pressure is often the first sign of toxemia. The majority of his patients showed albumin and high blood pressure at the same time. Elevated blood pressure preceded albuminuria in 50 of his cases, accompanied it in 113 cases, and followed it in 24 cases. One patient in 32 with a blood pressure of 130 to 140 mm. had toxemia, and one in 11 with pressure 140 to 150 mm. had it. Between 150 and 160 mm. the frequency of toxemia suddenly rose to more than one in three; while one-half of all between 160 and 180 mm. had toxemia, all above 180 mm. had toxemia. The abrupt rise in albuminuria and toxemia above 150 mm. shows that the danger point lies near here.

A rising blood-pressure curve is a better copy of the toxemia tracing than the albuminuria line, and it is fair to say that elevated pressure is more commonly an index of toxemia than albuminuria, and is apt to be an earlier sign. Newell emphasizes the fact that a rapid rise from a low level is more dangerous than a high stationary pressure.

Irving, in his report of 5,000 cases, found 64 patients suffering from toxemia, but only three who faithfully followed directions had eclampsia. All patients showing albuminuria, or a blood pressure above 130, were at once put on a meat-free diet, with restricted salt and increased amount of fluid, and was directed to take large doses of magnesium sulphate and return to the clinic in a few days. Should evidences of toxemia develop, the woman is admitted to hospital and put to bed, and the same treatment is more vigorously carried out. Should she fail to improve, and the condition grow worse, labor should be terminated.

The eliminative treatment was successful in 29 cases, and in 11 labor was induced. Nine patients out of 4,472, the number actually delivered in Irving's series, developed eclampsia, which is one in 497. Five were in primiparæ and four in multiparæ.

Six of the nine did not report at the clinic for one month before onset of seizures, and two of these died. Three eclampsia cases in all died. Only one had convulsions with a pressure less than 160 mm.;

her highest point was 140 mm., and the last reading of this patient was only 110 mm. This case again shows that a rising pressure from a low level, even though it does not pass the arbitrary danger point, may be a sign of impending danger. Eight had both albumin and increased pressure.

Irving's statistics show that only one of every 1,591 pregnant women died with eclampsia.

The death reports of the city of Norfolk show that in the last five years we have had 46 deaths from eclampsia, while 7,159 births are all that have been reported. It is claimed that one-third more births occur than are reported, the discrepancy being the fault of midwives, mostly, and some careless physicians. This would run our birth rate to 10,000, while the deaths from eclampsia would be the same (46).

As reports stand, we are credited with one death from eclampsia in every 156 births, and this is approximately about ten times as much as it should be. If we are given credit for the full number of births that actually do occur, then we have one death from eclampsia in every 218 cases, which is seven times as high as hospital cases show. In this city there are a large number of midwives; here I think lies the cause of this high death rate, as they pay no attention to anything except tying the cord, and filth. The physician is called only in time to sign the death certificate. These figures show that if they in any way benefit mankind they also kill a lot of women. It is plain, also, that it is every physician's privilege, as well as his duty, to report every birth.

Reports of two cases in my practice in last six months in which premature labor was induced are as follows:

Case I.—Mrs. C., age 28—one child, boy, twelve years ago—abortion three years before, due to patient using dirty catheter, causing violent infection and rupture of right tube with local peritonitis. Abdominal section was performed by the author, removing right tube and ovary, also appendix which was involved by exudate, and free drainage was instituted. The incomplete abortion was completed and the uterus was packed with iodine gauze.

The early part of the pregnancy was accompanied by some pain and dragging in the lower abdomen and nausea with vomiting for several months. A sister died in an eclamptic attack. Her blood pressure up to 7½ months was 125 to 130 mm., and a urine entirely free from albumin and casts. At this time the ankles began to swell and the patient had slight headache, with slight trace of albumin in the urine, the blood pressure was 140 mm. Diet, forced fluid, and salts with patient in bed, caused improvement, but in the course of two weeks the symptoms returned and persisted in spite of eliminative treatment, and the pressure ran up. I had seen this patient nearly dead once and did not propose to take another chance, so I dilated the cervix by the Harris method six different times, once under ether and three times with chloroform. The patient delivered herself three days after the first dilatation was started. The time between dilatations was about six hours, and chloroform was substituted for ether, as we could not get her to sleep with the first. Delivery at home of patient.

This woman did not have a single vaginal douch, and there was not a trace of infection. The child was born 20 days ahead of time, with no harm to either mother or child. Eclampsia might not have occurred, but no harm was done, and it is better to be on the safe side.

A woman who has the degenerative changes of eclampsia, even though she escape the convulsions, is not a well woman for a long time, if ever the same.

Case II.—Mrs. M., age 35—two children, 8 and 10. No other history. Early pregnancy was accompanied by only slight nausea. The woman took everything her so-called friends suggested to bring about an abortion. Everything progressed normally, however, up to nearly the ninth month, when suddenly she became edematous and the blood pressure, in spite of eliminative treatment, climbed rapidly to 170. There was no albuminuria, but the specific gravity of the urine dropped to 1008 and the twenty-four-hour amount was small.

The patient was taken to hospital and the cervix was dilated every three hours by the Harris method, five times in all, the first three times without an anesthetic and last two with ether. Patient delivered herself twenty-four hours after beginning induction; morphine ⅛ gr. with hyosine 1/200 gr. was given six hours before delivery. The child was born with the cord around its neck, which was slipped over the head. The baby very much cyanosed and refused to breathe for thirty minutes. Artificial respiration and breathing into and out of lungs through gauze finally started the breathing. No vaginal douches were used and an intrauterine swab on the third day, because of high temperature, proved the track to be absolutely sterile both by smear and culture.

This woman was delivered 30 days before time, but made an uneventful recovery, and the child is perfectly normal.

PELLAGRA: ITS ETIOLOGY AND TREATMENT *

By J. F. YARBROUGH, M.D.,

COLUMBIA, ALA.

On April 10, 1916, the writer published in the *Southern Medical Journal* an article on Pellagra, in which the etiology and treatment of the disease were discussed at length. In this paper I said: "Pellagra is an autointoxication, the result of a carbohydrate diet in which there is practically no protein. This carbohydrate or alcoholic material, when taken into the stomach, is quickly converted by the normal heat of the body into what distillers call 'sour mash.' The production of this 'sour mash' three times daily, for weeks and months, finally so cripples the metabolic activity as to permit this fermented material to be taken into the circulation without the necessary chemical changes. As a result, the victim's metabolic function is practically destroyed by eating alcohol, and the result is the varied and complex symptoms we call pellagra." After a more thorough study, and an intimate hospital acquaintance with the disease, and after many clinical experiments conducted in the hospital, I am thoroughly convinced that the correct etiology of the disease has been discovered.

The symptoms of pellagra are so familiar that it is unnecessary to enumerate them here; however, it might be well to call your attention to the fact that cases occur in which no dermatitis appears, and they may be easily overlooked, and the direst consequences follow.

The treatment of pellagra may be considered un-

*Read by invitation before the State Medical Association at Mobile, Ala., April 19, 1916.

der two heads—dietetic and medicinal. Too much stress cannot be placed upon the necessity of immediately eliminating all carbohydrate or alcoholic material from the diet. I wish to insist with all the earnestness at my command that the carbohydrates must be eliminated if recovery is to be expected. All treatment will prove futile so long as small quantities are allowed. I do not believe pellagra will ever be successfully treated by the general practitioner, because the diet cannot be controlled in the home. Contrary to the opinion of physicians in whom great confidence may be placed, diet alone is not sufficient to bring relief to these sufferers. A mild case of recent origin may be relieved in this way, but many of our patients would have gone promptly to their rewards if the diet had been the only means employed. The Gibraltar on which we mainly rely is dilute nitric acid, twenty to thirty drops in a glass of water, one hour before meals, or as nearly on an empty stomach as possible. Dr. Goldberger, in the *Journal of the American Medical Association*, February 12, 1916, throws out this challenge: "Hereafter, the clinician who would attribute therapeutic value to any drug or other remedy in the treatment of pellagra, should be prepared to show, what has not heretofore been done, that the curative effect claimed cannot be attributed to the diet."

I accept the challenge, and submit the following evidence:

Case I.—Mr. S. J., white, age 47, height six feet, weight one hundred and twelve pounds. Admitted September 15, 1915, exhibiting the following symptoms: Oral cavity typically pellagrous; ulcers covered inner surface of lips and under the tongue, fissures in the corners of the mouth, salivation. Characteristic dermatitis on the dorsal surface of the hands, forearms, face and neck. Severe burning of the hands, feet, and stomach. Profuse diarrhea, stool by count every forty minutes; diarrhea of more or less severity had persisted for the past three years. Arthritis of both ankles; at intervals, alarming dyspnea, and insomnia. Systolic pressure 180. Patient very weak, and could talk but little with great effort. Profoundly anemic—not a trace of pink shown anywhere. This man, not from choice but from necessity, had been living for the past six months on protein, raw eggs and sweet milk, as an ulcerated mouth would not tolerate solid food. On entering the hospital he was given two raw eggs and eight ounces of sweet milk every three hours, and at midnight, simply continuing his former diet. Medicinally he was given thirty drops of dilute nitric acid in a glass of water three times daily, on as nearly an empty stomach as possible. After the third day his stools were never more than two in twenty-four hours so long as he remained in the hospital. By the end of the first week, ulcers and salivation had disappeared. At this time the tips of his ears, nose, lips, and nails were distinctly pink,—the anemia disappeared as if by magic. He was dismissed at the end of the fifth week, seemingly well, having gained thirty-two pounds. Ninety days from the date of his dismissal he weighed one hundred and seventy-five pounds, and is now doing hard work in the field every day.

Case II.—Mrs. G. L., white, age 27, height five feet two inches, weight ninety pounds. Admitted December 1, 1915. Physical examination showed oral cavity typically pellagrous. Characteristic dermatitis on dorsal surface of the hands, forearms, and face. Constipation, insomnia, melancholia, and profound anemia. This patient was in the hands of a competent physician, who, seeing tne result of Dr. Goldberger's experiment with the convicts of Mississippi, placed this patient on a strictly protein diet, and she remained thereon until her life was despaired of. On entering the hospital the diet was continued, and the acid given, with the result within one week her ears, nose, lips and nails were distinctly pink. She was dismissed seemingly well December 25, having gained fifteen pounds, anemia gone—in fact exhibiting every symptom of health.

Case III.—Miss M. R.——, white, age eighteen, height five feet, weight ninety pounds. When taken ill in the Fall of 1913, she weighed one hundred and sixty pounds. This patient, during January and February, 1916, was treated in one of the best hospitals in the South, in a distant State. She remained there on diet treatment until her condition was regarded as hopeless, and sent home to die. On entering the hospital March 18, 1916, she presented the following symptoms: Characteristic dermatitis on hands, forearms, face, and dorsal surface of feet and lower limbs; oral cavity pellagrous, with ulcerations. Diarrhea, frequent fetid stools. Profound melancholia. Systolic pressure 90, very anemic, with a pulse of 40, almost moribund. She was put on the diet of raw eggs, milk, and orange juice. Thirty drops of dilute nitric acid in a glass of water was administered three times daily, and at midnight. Since the second day, her stools have not been more than two in twenty-four hours. At the end of the first week her mental condition had wonderfully improved, with nails, ears, nose, and lips showing pink. She is now in the hospital gaining more than half a pound every day.

Case IV.—Mrs. J. T.——, white, age thirty, presented herself for treatment December 15, 1915, exhibiting the following symptoms. Oral cavity pellagrous. Characteristic dermatitis on dorsal surface of hands and forearms. Diarrhea; nervous and irritable; very weak and anemic. This being an intelligent woman and living only a block from me, it was considered an ideal case on which to test the diet treatment. December 15, 1915, she was put on a strictly protein diet—milk, butter, eggs, beef, peas, bean bread, and vegetables. April 12, 1916, she presented the following symptoms: Oral cavity improved, tongue still had slick glazed appearance; constipation, no gain in weight, nervous symptoms improved; still weak and anemic.

Diet certainly did not relieve these patients, nor do I believe any quantity of the richest proteins the earth affords will alone produce such results as we have obtained in Cases I, II, and III. If time allowed, we could produce a great mass of additional evidence in support of our contention.

Of the more than one hundred cases treated in the hospital it has never required more than four weeks to seemingly relieve our uncomplicated cases. They regain their flesh, the anemia disappears, and they return to their several vocations. Dr. Deeks had a similar experience in the treatment of pellagra while in charge of the Ancon Hospital, in the Canal Zone.

If Dr. Goldberger's theory is correct, diet could not have been responsible for the rapid recovery of these patients, because he says in the article referred to: "Such observation as I have been able to make strongly suggest that the real recovery from an uncomplicated attack may not take place until after a minimum of about three or four months of full feeding of fresh animal proteins and legumes." Dr. Goldberger here admits that it requires a minimum of three to four months to obtain definite results from the diet treatment. If by the addition of nitric acid we obtain the same results in one-fourth of the time, it seems clear that this drug is a valuable adjunct in the treatment of the disease.

The following is abstracted from the article referred to in the *Southern Medical Journal:* "Probably the most important reason why this drug should be employed is the fact that the blood is found to be acid. The hemoglobin of an acid blood carries but little oxygen, hence the acute progressive anemia that quickly follows an attack of pellagra. The administration of nitric acid renders the blood quickly and positively alkaline. At once it assumes its normal function of carrying oxygen, and the anemia disappears as if by magic."

To prevent the possible conveyance of an erroneous impression, it might be well to explain what is meant by an acid blood. We all know that a great departure from its normal alkalinity would prove quickly fatal. However, there are conditions in which the blood very nearly, if not quite, reaches a

faint acidity. And I refer to this condition when speaking of an acid blood. Dr. George W. Crile recognized this condition in an article entitled, "The Kinetic Drive," recently published in the *Journal of the American Medical Association*, in which he says: "Oxygen is supplied by the lungs. If the blood be acid, oxygen cannot be carried by the hemoglobin. Energy transformation depends, therefore, on the maintenance of the alkalinity of the blood."

In an editorial article in the same journal, on "Alveolar Air and Acidosis," the condition of the blood I have tried to describe as found in pellagra is recognized, for the writer says: "Finally, however, the reserve supply of bases in the tissue is exhausted, and the increased acidity of the blood stimulates the respiratory center, causing increased aeration and a decrease in the carbon dioxide tension of the blood. The chief variations depend largely on the consumption of carbohydrate, which raises the amount. By virtue of the strong automatic regulation of the blood reaction, and the increased aeration of the blood resulting from the respiratory stimulation, the increased amount of non-volatile acid in the blood tends, therefore, to decrease the amount of carbon dioxide in the blood, and hence in the alveolar air. This is the condition called acidosis, and it is characterized clinically by air hunger, or dyspnea, stupor, delirium, vomiting, convulsions, and finally coma." The writer here describes the exact symptoms we find in many fatal cases. He also says that the consumption of the carbohydrates increases the acidity of the blood. This is the proposition for which we are now contending, and have contended for a long time.

Blood, deprived of its normal supply of oxygen, must of necessity deteriorate rapidly, and with it all of the normal functions of the body, particularly that of digestion. Alkalinity restored, the intake of oxygen quickly restores the sick and dying corpuscles. They spring into new life, giving tone and vigor to the entire body. Metabolic activity is regained, and the anemia rapidly disappears.

I frankly admit that I do not understand by what process nitric acid transforms an acid into an alkaline blood. One of America's foremost biological chemists is now bending his efforts to solve the problem. However ignorant we may be of how this transformation is accomplished, it does not alter the fact that it is done. The departure of the blood from its normal alkalinity in this disease is, I believe, the most important discovery made in the study of pellagra, because I am thoroughly convinced the carbohydrate diathesis referred to in my former article is the common parent of a number of allied disorders: Pellagra, muscular and articular rheumatism (other than gonorrheal or specific), nephritis, neuritis, cystitis, vaginitis (other than gonorrheal), leucorrhea, acne, eczema, and all allied conditions, are, I believe, the result of a carbohydrate diet. Nitric acid, together with proper food, is the golden key that opens wide the door to health and happiness.

Causes and Treatment of Perthes's Disease.—F. C. Kidner urges that osteochondritis deformans juveniles is really a mild infection of hematogenous origin, of the neck of the femur at the epiphyseal line; that the logical treatment to hasten recovery and limit destruction is the clearing out of this focus, and that mechanical treatment, which precludes weight-bearing should be faithfully carried out until the normal structure of the tissues of the head and neck of the femur has been completely restored, in order that deformity may be avoided.—*American Journal of Orthopedic Surgery.*

THE WASSERMANN REACTION IN TWO HUNDRED AND FIFTY-ONE TUBERCULOUS DISPENSARY CASES.

By W. RAY JONES, A.B., M.D.,

SEATTLE, WASH.

THESE were unselected cases coming to the public tuberculosis clinic of the city of Seattle with a ready-made diagnosis of tuberculosis. Seventy-three gave a positive reaction and one hundred and seventy-eight a negative one. The percentages by sexes were approximately the same in both the positive and negative reactions; *i.e.* 70 per cent. male and 30 per cent. female. The degree of the reaction in either sex is shown in the following table, + + + denoting complete inhibition of hemolysis.

	+	++	+++
Male	17	12	24
Female	4	3	13
Total	21	15	37

This gives 14 per cent. of all cases a + + + reaction, 20 per cent. a + + or stronger, and 29 per cent. a + or stronger.

The cases were divided into two classes; 189 coming from the public sanatorium where a Wassermann is a part of the routine examination, and the other 62 from the outpatient department where blood was taken to clarify the diagnosis. Among these 62; 30 were proven non-tuberculous, and of this 30; 19 or 7.6 per cent. of the total 251 were not tuberculous, but frank syphilitics masking as tuberculous. If these non-tuberculous and the incomplete cases from the outpatient department are eliminated and only the 189 routine cases counted; the figures drop to 11 per cent. + + + positive, 17 per cent. + + or stronger, and 25 per cent. + or stronger.

Two cases showed a hilus involvement only; a characteristic sign of pulmonary syphilis; but both of these had bacilli in the sputum as well as a positive Wassermann. Two of the positives were diagnosed tuberculosis on the physical findings and general symptoms, in spite of repeated negative sputum examinations, and one was treated as presumptive tuberculosis though the presence of this disease could not be substantiated even by physical findings. This 1 per cent. of the total gave more than a suggestion of lung syphilis or mediastinitis.

Ages varied from a sixteen-year-old girl giving a single + reaction who had signs of congenital lues, to a man of seventy with a + + blood and absolutely no symptomatic signs. The average age was 33 years.

Old scars, nerve signs, and symptoms, and the like were strangely absent, or could be directly attributed to the tuberculosis. Palpable post-cervical and epitrochlear glands, our most constant sign of syphilis, were almost invariably present in both positives and negatives, probably due to the emaciation, as all cases gave a history of loss in weight.

Occupations told nothing more than the occupations of a like number in the general charity dispensary.

Histories were absolutely worthless, as the women denied everything with vigor, and the men fearful of being refused treatment, admitted chancres in only a few cases. Those admitting a

probable infection were most often the weakly positive or negative reactions. One point in the family history might be considered, in that most of the positive married females were living separated from their husbands. Family difficulties had an amazing frequency among the positive married men also. This leaves a question as to what relation domestic discord and syphilis have to each other.

By nationality 66 per cent. of the negatives were American born and 44 per cent. foreign. The positives gave practically the same figures, and no one nationality showed a preponderance towards either positive or negative.

All blood examinations were made in the city bacteriological laboratory and after the original Wassermann technique. The cases were taken from the files of the tuberculosis division of the city health department, and due credit is given to the officials in that department for permission to consult the records and assistance in compiling these statistics.

No attempt is made at the present time to give the reason for such a high percentage of positives, nor to determine whether the weaker reactions were due to syphilis, or as some claim to the tuberculosis.

1105 Cobb Building.

Medicolegal Notes.

Malpractice, Insufficient Evidence of. — Action was brought for malpractice by injuring the neck of the plaintiff's femur by negligently manipulating her leg, causing it to be shortened about two inches and to turn outward. The plaintiff had been suffering from chronic sciatica for about three months, during which time she had only been visited twice by a doctor to administer a necessary narcotic. The plaintiff was called in to operate, which he did by manipulating the leg and flexing the joints in order to break up the adhesions at the hip and knee joints and along the sciatic nerve. All the physicians who testified in the case stated that the condition of the plaintiff's leg was the result of a tubercular condition of the upper end of the femur, which destroyed a portion of the bone, permitting the muscles of the leg and hip to shorten the leg to the extent that the bone was destroyed by the tuberculosis. There was no evidence that the operation was not the proper one, or of any negligence in the way in which it was performed, so that, unless the doctrine of *res ipsa loquitur* could be applied, there was no evidence of negligence to go to the jury. Even the medical expert for the plaintiff testified that if there had been a fracture at the neck of the femur at the time of the operation it would have been evidenced by an immediate shortening of the leg and eversion of the foot, but that the latter would also have resulted from a breaking up of the adhesions, and that the rotation of the foot outward alone after the operation did not indicate a fracture any more than a reduction of the adhesions. There was no evidence of an immediate shortening of the leg; so that upon the only theory advanced by the plaintiff that could have indicated a fracture in the operation, the evidence sustained but one of the two necessary elements. The doctrine of *res ipsa loquitur* has no place in a case like this. The court quoted from Ewing vs. Goode (C. C.), 78 Fed. 442, where Judge Taft said: "A physician is not a warrantor of cures. If the maxim *res ipsa loquitur* were applicable to a case like this, and a failure to cure were held to be evidence, however slight, of negligence on the part of the physician or surgeon causing the bad result, few would be courageous enough to practise the healing art; for they would have to assume financial liability for nearly all the 'ills that flesh is heir to.'"

The defendant was employed for one trip only to perform the operation. The plaintiff lived at a distance of ten miles away. An agreement was made as to what his fee should be in case other visits were necessary, and he told the plaintiff and her husband to notify him if he should be needed. He was never called subsequently. It was held that his services were concluded by assent when the operation was performed, and the case did not come within the rule that a doctor may not, after accepting an employment, abandon a patient without reasonable opportunity to procure another physician.—Miller vs. Blackburn, Kentucky Court of Appeals, 185 S. W. 864.

Compensation for Services — Failure to Take Blood Test.—In an action by a surgeon to recover for professional services it appeared that the patient was suffering from exophthalmic goiter, and upon consulting the plaintiff was advised by him to go to certain specialists for treatment. Not desiring to do so, the patient and her husband requested the plaintiff to perform the necessary operation. The patient was thereupon sent to the hospital, and in a day or two the operation was undertaken. It progressed until about half the goiter had been removed, when the patient died. The defendant, over objection, was allowed to introduce evidence that no blood test was taken prior to the operation, and that such a test was usual to determine the oxygen-carrying power of the blood, which if below a given point renders an operation of this kind extra-hazardous. On appeal this was held an error, as there was no evidence that the blood of the patient was below the required oxygen test, nor was there any attempt to show that the failure to take the blood test contributed to any extent to the patient's death. Before a charge of negligence can be sustained against a physician or surgeon there must be some evidence that the failure to use proper skill, either in the thing done or in the thing left undone, was the proximate cause of injury to the patient. In other words, there must be some connection between the act and the result complained of. Here there was none. It did not appear that it was the custom in that locality to take blood tests. A physician or surgeon does not guarantee to cure his patient, or that his treatment will be successful. And the plaintiff's remark, after he had urged her to go to the specialists and she had refused, "Well, if you are willing to take a chance with me I will take a chance with you," did not show that the plaintiff agreed to demand compensation only in the event of a successful operation. Judgment for the defendant was reversed. —Harvey vs. Richardson, Washington Supreme Court, 157 Pac. 674.

Privileged Communications.—The Washington statute prohibits a physician from testifying without the patient's consent to any information acquired in attending such patient which was necessary to enable him to treat such patient. In an action for personal injuries it appeared that the plaintiff's physician visited him, expecting to prescribe. The defendant asked him on the witness stand whether the plaintiff was up and dressed; whether he was moving about; whether he was staggering, walking in a hesitating manner, reeling, or showing any signs of nausea or dizziness. The defendant attempted to justify the questions because the plaintiff had previously related that he took from this doctor a draught of medicine which put him to sleep. It was held that this did not justify the admission of the physician's testimony, as what the plaintiff said was not an attempt to describe the doctor's treatment or theory of the disease or to quote the doctor while shutting his mouth.—Wesseler vs. Great Northern R. Co., Washington Supreme Court, 157 Pac. 461.

Proof of Value of Services Rendered. — Action was brought by a physician upon an account rendered by him as a licensed physician, and also upon an account assigned to him which covered services as a pathologist rendered by the assignor. The defendant had verbally agreed to pay the claims of both the physician and the pathologist for services to her son when in the State of California. It was held that the agreement was not void under the statute of frauds, though not in writing. There was no dispute about the services having been rendered by the physician, that he charged the plaintiff $300 therefor, that the services were worth that sum, that he was paid on his individual account $125, leaving a balance unpaid of $175. For this he was held entitled to recover. But there was no proof of the value of the services rendered by the pathologist. In the absence of an express agreement, one who brings to such a service as was rendered by him due care and skill can recover the reasonable and customary price therefor, but such reasonable and customary fee must be shown by competent evidence. Proof of the price charged without any proof of the value of the service performed was not sufficient, and did not meet the test. —Johnson vs. Jones, Ind. Appellate Court, 112 N. E. 830.

TWO LITTLE-KNOWN FACTS ABOUT MORPHINE.

EVERY practising physician passes through two phases in his daily dealings with certain drugs, especially those remedies known as specifics and those which act upon some particular symptom, as morphine does upon pain. The first phase is the gradual increase of faith in the medicine in question until he comes to accept it as practically infallible. And then sooner or later come unaccountable instances of failure and his divine confidence is rudely shaken.

This is true of morphine. This powerful drug is duly hedged about with restrictions in the mind of the young practitioner so that he hesitates to use it except it be absolutely necessary. But now and then it becomes a *dernier ressort* and after a number of experiences of its speedy and effective analgesic action he comes to hold it in reserve as the ace of trumps. Among the cases which now and then require opium are the worst ones of migraine. Theoretically, of course, we do not use opium in migraine and practically, thanks to the anilin derivatives, it is indeed rarely necessary. Once in a while, however, it is necessary to resort to this drug, and very rarely it is not effectual. It is probably a conservative statement that every physician who has practised more than ten years has met with cases of migraine which did not yield to morphine.

Now as to the explanation. Adler[1] says that these cases are neurotic and the migraine is entirely psychic in origin. The affliction ministers to the neurotic's desire to dominate his environment by making all his family and friends anxious to wait on him and he does not readily yield this advantage. If this is the true analysis of such a migraine we can readily see why drugs, even morphine, are ineffectual. The only way to handle the situation is to educate the neurotic to perceive that he undergoes his suffering merely to subjugate others and that these are far more effectual and socially useful ways of maximating his ego-consciousness (as Adler puts it) than by making every one around him miserable.

So much for a psychical aspect of morphine. A physiological peculiarity connected with the drug has been recently reported by Drs. McGuire and Lichtenstein,[2] who have observed approximately 12,000 cases of drug addiction in the Tombs prison during the past twelve years. They claim that many of the women opium habitués present a wonderful growth of hair. Not only is it long, but thick and oily. It is common, say these physicians, to see female addicts with hair reaching to the ground. They explain this as being a purely nutritive process; opium and its derivatives stimulate the numerous sweat glands distributed to the scalp and the roots of the hair, increase the moisture of the scalp, and thus cause a growth of hair.

[1] "The Neurotic Constitution," by A. Adler, New York: Moffat, Yard and Co., 1916.

CARBON MONOXIDE POISONING.

CARBON monoxide gas is the most frequent cause of poisoning as noted in the cases brought to our hospitals, and yet its action and, in consequence, the treatment of the poisoned patient, have been subject to a great number of misconceptions which have doubtless resulted in the loss of a good many lives. These facts are well brought out in an article by Yandell Henderson in the *Journal of the American Medical Association*, August 19, 1916. It is a very general belief that the compound formed by the union of carbon monoxide and hemoglobin is such a stable one that it is useless to attempt to break it up by the usual therapeutic means. As a result of this belief it has been the accepted mode of treatment to bleed the patient in order to remove the toxic compound from the circulation and to replace the blood thus removed by saline solution or the blood from a healthy person.

Henderson details experiments which show that carbon monoxide-hemoglobin is not the stable compound that it has been thought to be, but that the carbon monoxide may be displaced by subjecting the blood to a large mass of good air or air enriched by oxygen. Furthermore, he found that persons who had been poisoned with illuminating gas (the poisonous constituent being carbon monoxide) when removed to an atmosphere of fresh air, purified their blood of the toxic gas within half an hour at most. "Practically all of the carbon monoxide is thus eliminated, and the hemoglobin fully restored in three or four hours." He emphasizes the conclusion that phlebotomy is therefore an illogical and possibly dangerous procedure, especially as it is almost always performed more than an hour after the patient is removed from the influence of the gas. His observations also explain why it is generally so difficult satisfactorily to demonstrate the presence of carbon monoxide-hemoglobin in the blood obtained by such phlebotomy. According to this author the symptoms are due to the effect upon the central nervous system of the deprivation of oxyhemoglobin during the period when the poisonous gas was present. The harmlessness of temporary "gasing" was demonstrated in the Pike's Peak expedition of which the author was a member. The carbon monoxide method for the estimation of blood volume was used, and although the members of the party repeatedly inhaled sufficient of this gas to

[2] "The Drug Habit," by Frank A. McGuire, and Perry M. Lichenstein, MEDICAL RECORD, July 29, 1916

combine with about 20 per cent. of their hemoglobin, no ill effects were manifest.

The treatment then is quite simple. Henderson says: "Thus it appears that about all that can be done in cases of carbon monoxide poisoning is to administer artificial respiration when the patient's own breathing has failed or is feeble, to administer oxygen for half an hour (longer is useless), to keep them warm if their temperature has fallen, to supply water to the system, preferably by a Murphy drip, and otherwise to give them good nursing and such symptomatic treatment as may be called for." He also suggests that the coma may be allied to that found in acidosis and that the intravenous administration of sodium bicarbonate may be of value. Thus it seems that the prognosis is fixed at the moment the patient is removed from the influence of the gas and that the best results are to be obtained, as in so many other pathological conditions, by abstaining from too active interference.

ATRIOVENTRICULAR DISSOCIATION.

Atrioventricular dissociation is by no means the same as the Stokes-Adams syndrome, although in the majority of cases the latter belongs to the former, or, in other words, such dissociation is the principal cause of the syndrome. Dissociation often occurs in the absence of the nervous crisis held to characterize heart-block. Again, while the pulse in dissociation may be as low as 30 to 40, this condition must not be confused with bradycardia. Routier (review in *La Riforma Medica*, July 10) recognizes three degrees of atrioventricular dissociation, viz., (1) Simple blocking from arrest of the stimulus of contraction in the auricle; the response of the ventricular contraction is then wanting. (2) Complete dissociation, in which auricle and ventricle act independently of each other, from separate stimuli. (3) Incomplete dissociation which is simple blocking with the addition of occasional autonomous contractions of the ventricle. Dissociation may be due to some anomaly of conduction or to some disturbance of excitability. The principal cause under the former head is organic disease involving the bundle of His. This state of affairs, being progressive, tends to cause complete dissociation. In the second place certain poisons exert a selective action on the bundle of His (muscarine, physostigmine, digitalin, aconitine). Asphyia suspends the function of the same structures. Finally the fibers of His are rendered refractory by too rapid and frequent stimulation of the auricle, and we see arrhythmia develop as in auricular flutter and tachysystole. Under the head of disorders of excitability come hyperexcitability of the autonomous centers, of the ventricle, as in the case of atropine poisoning, and an opposed state of autonomous slowing of the ventricle. In certain cases the ventricle remains refractory to this over-stimulation. Other disorders of excitability are seen in the failure of extrasystole of auricular origin, and also in the compensatory repose of the ventricle after an extrasystole. Routier does not recognize dissociation of purely vagus origin, but vagal hypertonia may act in connection with other factors in causing complete dissociation.

We are still in ignorance of the part played in dissociation by the sympathetic fibers—the plexuses of which are scattered throughout the myocardium and about the coronary arteries. Holding the view that adrenalin acts selectively upon these fibers Routier has been able to demonstrate an action by them upon the phenomenon of dissociation. An acceleration is due to the action of adrenalin on the terminals of the coronary plexuses, but the block can be overcome only by an action of the sympathetic fibers in His's bundles, which can respond only when enough muscle remains for a contraction wave. Routier is satisfied that a purely muscular lesion of the His bundle cannot lead to dissociation and that the latter is in the main of nervous pathology.

LATE OPERATIONS FOLLOWING MEDICAL TREATMENT IN GUNSHOT WOUNDS OF THE ABDOMEN.

After a careful study of the results obtained with and without operation in penetrating wounds of the abdomen, referred to in the Medical Record of March 11, 1916, Quénu made out a strong case for early operation and apparently showed that when the projectile actually entered the abdominal cavity it was very probable that the individual who survived under medical treatment would come to operation sooner or later because of complications of one sort or another. In another communication on this subject to the Société de Chirurgie of Paris (*Revue de Chirurgie*, February, 1916), Quénu says, that, as a result of further study, he has become still more convinced of the correctness of his earlier conclusions.

In connection with this contention that in medically treated cases with recovery operation may be only deferred, a case reported by A. Chalier (*Le Progrès Médical*, July 5, 1916) in which a rifle bullet had to be removed after having been encysted in the omentum for 18 months is of considerable interest, particularly as Chalier states that somewhat similar cases have been reported by Walther, Goullioud, and Quénu. In Chalier's case there had been vomiting and marked meteorism for the first two days after receipt of the injury but these subsided under the influence of rest and proper diet. No operation was done during the three and one-half months the patient was in the hospital. On various occasions since then he had had colicky pains and symptoms of subtotal obstruction and he entered Chalier's service complaining of these symptoms, pains in the lower extremities, and difficulty in walking. Radioscopic examination showed that the projectile was fixed in the abdominal cavity a little in front and to the right of the promontory of the sacrum, not embedded in the bone. Upon operation the bullet was found encysted in the omentum, which latter was strongly adherent to the posterior parietal peritoneum. The cystic pouch, containing the bullet and a quantity of reddish fluid, was resected and convalescence was uneventful. Chalier considers it strange that the bullet had been tolerated for 18 months without grave consequences; yet as he says, fusion of the omentum

to the posterior abdominal wall gave rise to intermittent mechanical troubles which might have been so suddenly increased at any time as to have required emergency operation.

The Tobacco Habits of Schoolchildren.

An illuminating glimpse into the possible diversions of our boys and girls while away from sight at school is afforded by a recent report* which contains the results of an investigation by Drs. Stiles and Richards of the Public Health Service. To be sure the children in question were largely drawn from a rather low stratum of society, but in the present democratic arrangement of our public schools the girl from a refined surrounding is so apt to rub elbows with the hooligan from Goat Alley that the fear is rather that she will absorb the mannerisms of the gutter from him than that he will improve by her example. Drs. Stiles and Richards examined 2,215 pupils, ranging in age from 4 to 20 years. They were divided into two groups, those who had toilet facilities in the house being known as the sewerage, or for short the "S" group, and those who had an outside privy only, the "P" group, this grouping being considered roughly indicative of the cultural level obtaining in the household. It was found that no girls chewed or smoked tobacco. About one-half of 1 per cent. in the S group dipped snuff and slightly less than that in the P group. Only one boy in the 1,043 examined took snuff and it was not ascertained whether or not his home had plumbing. About 1½ per cent. of the boys in the S group chewed and 3 per cent. in the P group, but 6.5 per cent. of the S group smoked, while only 5 per cent. of the P group indulged themselves thus. The tender age of some of these devotees of nicotine is surprising. Thus there were three boys of 11 years who chewed, two of 10 years, two of 9 years, and one of only 8 years. There were six 10-year-old boys who smoked, three 9-year-old ones, one of 8, and one of 6 years! Moreover, two boys had begun the habit at 6 years and one at the age of 3. This last prodigy will probably shatter the retro-barn-door record of all of us, no matter how precocious. There was one 12-year-old girl who dipped snuff, one 11-year-old one, and a boy and a girl of 9 who indulged. One girl had begun this habit at the age of 4 and two at the age of 3. Of course, the inception of habits such as the above at the early age quoted can only mean gross neglect of parental duties, but the fact remains that if the conditions found in the city studied may be considered as at all typical the profession must change its attitude in regard to the tobacco habit and not arbitrarily rule out any age as too young in considering the possibility of its influence in a given case.

Points of Attack of Tuberculosis.

In the nation-wide battle against tuberculosis any information from authentic sources about this plague is of value, therefore we welcome an article, contributed by Dr. George M. Kober to a recent Public Health Report, dealing with the routes by which the bacillus may enter the body. Infection by inhalation is the most frequent method, according to Kober. The germs may be propelled into the atmosphere by talking, coughing, or sneezing. The dangerous zone about a patient with tuberculosis extends 3 feet in every direction, Flügge says. The next most frequent way is to take them in through the digestive tract. Eating utensils may be the media of transmission; milk and meat are frequently infected. Analyses of a number of samples of milk from dairies in Washington, D. C., showed that 6.72 per cent. of them harbor germs. This, of course, brings up the question of bovine and human tubercle bacilli. It has recently been said that the former may be changed into the latter by a prolonged residence in the human body. Among the things which Kober indicts are allowing babies to creep on a dirty floor, long skirts, and insanitary dwellings. Apropos of the latter he quotes the famous "lung blocks' of Biggs of New York and Flick of Philadelphia. Flies are also a frequent source of infection, to add another argument to the scores against this insect. Dust is a favorite habitat of the germ—in the United States and Germany just twice as much of the disease has been found among workmen whose trades were dusty in nature, although in this case the dust acts chiefly as an irritant, thus preparing the soil for growth of the bacillus. On the other hand, damp soils and houses predispose to tuberculosis. Kober also calls attention to the amazing prevalence of the germ. Thus recent autopsies by Hamburger and Monti in Vienna have shown that 95 per cent. of children actually have the germ in their systems by the time they are twelve or thirteen. According to Nagels 97 per cent. of all people have foci of tuberculosis at one time or another in their lives. City dwellers should remember that the greater the park space in their communities the less will be the tuberculosis, and they should encourage the city fathers to increase these breathing spaces rather than diminish them. It is gratifying to note that the death rate has dropped from 326 per 100,000 in 1880 to 147.6 in 1913. Dr. Kober optimistically believes that we are on the way to stamp out the disease altogether.

The Elastometer.

Our methods for recognizing the degree of edema have heretofore been crude. Changes in the body weight have been utilized to some extent, especially in connection with degrees not palpable to the finger. Roughly speaking a gain in weight in the absence of nutritive factors may imply a condition of waterlogging. Widal claimed that a gain of over 15 pounds meant a state of edema. In ordinary palpation the milder degrees cannot be perceived, and Schade's elastometer therefore is regarded as an improvement in the diagnosis of edema. According to an article by Schwartz in *La Riforma Medica* for July 10, this consists of a disk which when sunk into the skin and subcutaneous tissue registers the changes in elasticity by means of a lever acting on a recording cylinder. Several similar disks are used in the vicinity of the first and other readings obtained. The first disk is weighted, while the control disks are not. If normal elasticity is present the skin when compressed returns quickly to the normal, as shown in the curve registered on the cylinder; but if the disk is weighted the curve is replaced by a horizontal line and when the weight is removed there is a perpendicular fall. In edematous tissues with loss of elasticity the curve ascends after the use of the weight, but more slowly; when the weight is removed the curve descends, but not as in normal tissues is its original base.

* "Tobacco and Snuff. Their Use by White School Children in the City of X," by C. W. Stiles and D. N. Richards, M.D.

News of the Week

Poliomyelitis on the Decline.—A considerable reduction in the number of cases of poliomyelitis in all the boroughs of New York City has been evident during the last few days, and it is believed that the worst of the epidemic is over. The total number of cases up to August 29 was 7,908, with 1,889 deaths. For the week ending August 26, 753 cases were reported in all boroughs, as compared with 912 during the week ending August 19, and 1,151 in that ending August 12. The decrease has been especially noticeable in Brooklyn, where the epidemic started. Outside of New York City there were reported in the State up to August 26, 1,802 cases with 199 deaths. The State Department of Health now has sixteen diagnosticians and sixteen sanitary supervisors in the field, and is sending specially employed consultants for inspection and visitation to seventeen hospitals scattered throughout the State. In New Jersey 2,241 cases were reported up to August 26. The date of opening the public schools in New York has not yet been determined, and the question of deferring the opening of Columbia University is under consideration.

City Death Rate.—The New York City Department of Health points out that in spite of the severe epidemic of infantile paralysis this summer the death rate of the city for the first thirty-four weeks of the year was but very slightly in excess of that for the same period of last year, the respective figures being 14.57 and 14.53 per 1,000 of population. This increase represents only four deaths per 100,000. In every age group except that of children under five years of age there was a decrease in the death rate, proving that the general sanitary condition of the city is better this year than last.

Dr. Louis Livingston Seaman, president of the British War Relief Association, sailed from New York on August 26 for London. He will supervise the work of the association in England, France, and Belgium.

Dr. Murphy's Estate.—It is reported that the estate left by the late Dr. J. B. Murphy of Chicago will total 1,125,000, of which $1,000,000 is in real estate.

Death of an Old Indian.—Ayoushakatsagom, a veteran Cayuse Indian, died at Pendleton, Ore., on August 23, at the reputed age of 120 years. His memory went back to events which occurred during the war of 1812.

Plattsburg Medical Camp.—Three sessions of the Medico-Military Instruction Camp at Plattsburg, N. Y., will be held this summer, each lasting two weeks. The first began on August 10, the second, on August 24, and the third will open on September 8. The course for each session covers military surgery in the field. Lieutenant-Colonel Henry Page and Major P. W. Huntington are the officers in charge.

The Sanest Fourth.—For the fourteenth year the *Journal of the American Medical Association* has collected and published statistics of the accidents occurring in the United States as a result of the Fourth of July celebration. The report shows most strikingly the good effects of the campaign for a safe and sane fourth which has been carried on for some years. In 1903, the year in which the first collection of statistics was made, 466 deaths were reported as due to fireworks; in 1916 only 30 deaths were so reported. In the former year the injuries numbered 4,449, and in 1908 the number rose to 5,623, while in 1916 the total casualties were only 850. The deaths due to lockjaw declined from 406 in 1903 to none in 1916, and not one case of blinding was reported.

Five Babies in Seven Months.—Mrs. Julius Cojenski of Greenwich, Conn., is reported to have established a record in having given birth to triplets and seven months later to twins. None of the children have survived. Although only twenty-seven years old, the woman is said to have been the mother of thirteen children, of whom only five are living.

Association of Railway Surgeons.—The twenty-sixth annual session of the New York and New England Association of Railway Surgeons will be held at the Hotel McAlpin, New York, on Wednesday, October 18, 1916. A very interesting and attractive programme has been arranged. Dr. William S. Bainbridge will deliver the address in Surgery, taking for his subject the Cancer Problem. Railway surgeons, attorneys, and officials, and all members of the medical profession are cordially invited to attend. Dr. D. H. Lake of Kingston, Pa., is the president of the association, and Dr. George Chaffee of Little Meadows, Pa., is the corresponding secretary.

American Association for Clinical Research.—The eighth annual meeting of this association will be held at the Hotel Majestic, New York, on September 28 to 30, 1916, under the presidency of Dr. Daniel E. S. Coleman, New York. An interesting programme has been prepared, and clinics will be held daily at the Flower and Metropolitan Hospitals. Further details may be obtained on application to the permanent secretary, Dr. James Krauss, 419 Boylston Street, Boston, Mass.

Caledonia County (Vt.) Medical Society.—At the annual meeting of the society held at St. Albans on August 11, the following officers were elected: *President*, Dr. Frank E. Farmer, St. Johnsbury; *Vice-President*, Dr. David E. Brown, Lyndonville; *Secretary-Treasurer*, Dr. Hugh H. Miltimore, St. Johnsbury.

Gifts to Hospitals.—St. Mary's Hospital, Philadelphia, has received from Mr. George Nevil a gift of $5,000 for the endowment of a free bed.

By the will of the late Mr. Hall Engles of Philadelphia the following bequests are made to institutions in that city: To the Pennsylvania Hospital, the Protestant Episcopal Hospital, the Presbyterian Hospital, the Polyclinic Hospital, the Jefferson Hospital, and the Samaritan Hospital, $10,000 each; to the Philadelphia Home for Incurables, the Jewish Hospital Association, and the Medico-Chirurgical Hospital, $5,000 each.

Convention of Colored Nurses.—The ninth annual convention of the National Association of Colored Nurses was held in New York on August 15 to 17, with 160 delegates in attendance.

Study of Malaria.—The International Health Board of the Rockefeller Foundation has announced that it is conducting two sets of experiments to determine how effectively malaria may be controlled in a temperate climate under conditions prevailing in typical farming communities of the Southern States. The first of these experiments, to test the practicability of malaria control by detecting carriers and freeing them of the parasites, is being carried on at Bolivar, Miss., under the direction of the Mississippi Board of Health. The second set is being conducted in Arkansas in cooperation with

the United States Public Health Service, and has for its object the testing of the practicability of malaria control by a combination of relief measures. In neither case will the experiments include the extermination of mosquitos by major drainage operations.

Hospital Ship to Moros.—With the cooperation of the Philippine Government, the Rockefeller Foundation is preparing to send a hospital ship to the Sulu Archipelago for the treatment of the Moros and members of allied tribes, many of whom have been found to be suffering from skin diseases, malaria, hookworm, dysentery, and other ills. In Mindanao and Jolo, it is said, the Moros have been reached to some extent by the dispensaries, but the great bulk of the population still stands in need of medical service. The ship, which is now being equipped, will be sent out for a five years' cruise.

Red Cross Unit Sails.—Consisting of ten surgeons and twelve nurses in charge of Dr. Daniel Fiske Jones of Boston, the third Harvard Red Cross unit sailed from New York on August 17 for Liverpool. The party will be sent direct to the British Expeditionary Base Hospital No. 22 on the French front, and will relieve the first and second units, whose terms of service have expired.

Obituary Notes.—Dr. Ezra Bradway Sharp of Camden, N. J., a graduate of the University of Maryland, School of Medicine, Baltimore, in 1888, died at his home on August 24, aged 55 years.

Dr. Wilbur Lee Pepper of Philadelphia, a graduate of the Jefferson Medical College, Philadelphia, in 1892, and a member of the American Medical Association, the Medical Society of the State of Pennsylvania, and the Philadelphia County Medical Society, died at Reheboth Beach, Del., on August 18, aged 46 years.

Dr. Andrew L. Van Patten of Los Angeles, Cal., a graduate of the Hahnemann Medical College and Hospital, Chicago, Ill., in 1876, died at his home, after several months' illness, on August 3, aged 71 years.

Dr. John M. Eager of the American Sanitary Office, Naples, Italy, died at his station on August 17, aged 52 years. Dr. Eager was graduated from the College of Physicians and Surgeons, New York, in 1888, and was appointed to the United States Public Health Service, in which, at the time of his death, he held the rank of surgeon, in 1892. He was a member of the American Medical Association.

Dr. Carl V. Cole of Lake City, Minn., a graduate of the University of Minnesota, College of Homeopathic Medicine and Surgery, Minneapolis, in 1904, was killed in an automobile accident on August 7, aged 39 years.

Dr. Ozias Willard Peck of Oneonta, N. Y., a graduate of the Yale University School of Medicine, New Haven, in 1857, consulting physician to the Aurelia Osborne Fox Memorial Hospital, Oneonta, a surgeon in the United States Army during the Civil War, health officer of Oneonta for twenty-six years, and a member of the New York State and Otsego County Medical societies, died at his home on August 4, aged 81 years.

Dr. John M. Crawford of Cincinnati, Ohio, a graduate of the Pulte Medical College, Cincinnati, in 1879, consul general to Russia during President Harrison's administration, and a former president of the Western Academy of Medicine, died at his home on August 13, aged 72 years.

Dr. Harry D. Barnitz of San Antonio, Tex., a graduate of the Georgtown University School of Medicine, Washington, in 1880, former president of the Board of Health of San Antonio, and a member of the State Medical Association of Texas and the Bexar County Medical Society, died at his home, after a short illness, on August 6, aged 63 years.

Dr. Ulysses G. Grigsby of Perry, Iowa, a graduate of the Eclectic Medical College, Cincinnati, Ohio, in 1896, died as the result of injuries received in an automobile accident, on July 27, aged 48 years.

Dr. Horace W. Coombs of Cave City, Ky., a graduate of the Eclectic Medical College, Cincinnati, Ohio, in 1870, died at his home, after a long illness, from cancer of the stomach, on August 3, aged 69 years.

Dr. Frank Hammett Holt, superintendent of the Michael Reese Hospital, Chicago, since 1915, a graduate of the Harvard University Medical School in 1899, a member of the American Medical Association, the Illinois State Medical Society, the Chicago Medical Society, and the Massachusetts Medical Society, and formerly superintendent of the Boston City Hospital, died at his home after a short illness, on August 3, aged 47 years.

Dr. Lyman Beecher Shehan of Superior, Wis., a graduate of the Medical School of Maine, Portland, in 1884, died at his home, after a long illness, on July 28, aged 61 years.

Dr. James D. Weaver of Eatonton, Ga., a graduate of the College of Physicians and Surgeons, Baltimore, in 1882, and a member of the Medical Association of Georgia and the Putnam County Medical Society, died at his home as the result of injuries received in an automobile accident, on August 5.

Dr. Kenneth D. Wise of Los Angeles, Cal., a graduate of Jefferson Medical College, Philadelphia, in 1865, died at his home after a lingering illness, on July 31.

Dr. Clinton De Witt Van Dyck of New York, a graduate of the Albany Medical College, Albany, N. Y., in 1879, a member of the New York State and County Medical societies, and for twenty-six years a medical supervisor of the Metropolitan Life Insurance Company, died suddenly from apoplexy, at Atlantic City, N. J., on August 10, aged 61 years.

Dr. Edward Kerschner of Hagerstown, Md., a graduate of the New York University Medical College, New York, in 1861, and since that time a member of the medical service of the United States Navy, serving through the Civil War and retiring a few years ago with the rank of Medical Inspector, emeritus professor of naval, military, and state hygiene in the New York Post-Graduate Medical School, New York, died at his home, after a brief illness, on August 20, aged 77 years.

Dr. Thomas Powell of Los Angeles, Cal., a graduate of the New York Medical College, New York, in 1858, and a member of the American Public Health Association, and the American Association for the Study and Prevention of Infant Mortality, died at his home, suddenly, on August 18, aged 78 years.

Dr. William Jefferson Rowe of Buford, Ga., a graduate of the Medical College of Georgia, Augusta, in 1887, died, suddenly, at the home of his daughter in Flowery Branch, Ga., on August 12, aged 60 years.

Dr. Wooster Beach of Westchester, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1854, and a founder and first president of the Medico-Legal Society of New York, died at his home on August 6, aged 83 years.

Correspondence.

ADRENALIN IN POLIOMYELITIS.

To the Editor of the Medical Record:

Sir:—During the course of an epidemic of a disease the therapeusis of which is still unsettled, it would appear wise to report cases upon which the newer procedures were tried, that the apparent results of such procedures may stimulate or discourage further application.

The following three consecutive cases of infantile paralysis were seen in consultation. The treatment consisted of adrenalin administered intraspinally, after the withdrawal of cerebrospinal fluid and in one case by the use of immune serum in addition.

Case I.—Boy, 6 years (bulbar type); ill three days, temp. 105°, glands enlarged at angle of jaws; supposed to be suffering from nasopharyngitis. The symptoms were vomiting, inability to swallow, irregular respiration, involuntary evacuation of urine and feces. The child was in coma, there was retraction of head, the occiput resting upon spine, the sclera only showing; respiration of the Biot type, Macewen, Brudzinski and Kernig signs present. Knee jerks absent, temp. 105°, pulse 120, respiration varying from 1 to 30 per minute, condition growing constantly worse. Spinal puncture performed and 70 c.c. clear fluid withdrawn, 6 c.c. 1:1000 adrenalin administered by gravity, convulsive twitching followed procedure for several hours. Six hours later condition was no worse than when puncture was done; a second puncture was made, and was a dry tap, although repeated attempts were made to withdraw fluid; no adrenalin was administered at this time. The condition continued to improve. After 12 hours there was a short period of consciousness; the child was able to swallow teaspoonful doses of water; respiration was less irregular. Eighteen hours after the withdrawal of fluid and administration of adrenalin the child was conscious, rigidity was almost absent, he swallowed well, respiration was regular, temp. 99°, and except for weakness of all muscles the boy was apparently not very ill. Three weeks after onset he was entirely normal except for slight weakness in the lower extremities, which is growing less daily, and which does not interfere with walking.

Case II.—Boy, 4½ years (bulbar type); symptoms similar to those in Case I except that respiration was not so seriously affected. An intraspinal adrenalin injection was given 48 hours after onset of acute symptoms, and repeated four times. Immune serum was once administered intraspinally. Recovery from severe symptoms required 4 days. Two weeks later the boy was entirely normal except for slight weakness of the external recti muscles of both eyes.

Case III.—Boy, 2½ years (spinal type); paresthesia marked; ill 5 days with irregular temperature and symptoms. There was slight rigidity of the neck; Brudzinski and Kernig signs present, knee jerks absent. Paralysis of all extremities and muscles of chest; involuntary evacuation of urine and feces. Temp. 103°, pulse 130, respiration regular but difficult. Spinal puncture was performed 24 hours after acute symptoms appeared—60 c.c. clear fluid withdrawn, and adrenalin administered as above; this was repeated once. Temperature normal after 72 hours. Fourteen days after the first puncture there was complete restoration of the upper and left lower extremities, with partial restoration of the muscular activity of the right lower extremity.

The foregoing cases are briefly reported, not as showing results of treatment, but to place on record the experience with a procedure which is apparently harmless and full of promise. The only untoward result of this therapeutic measure was a rather severe urticaria appearing within twenty-four hours in Cases I and III.

In contrast with the results in the foregoing cases are five cases of this disease seen prior to them in which no intraspinal injections were given. Two died of respiratory paralysis. One had a spastic paraplegia of both lower extremities after six weeks. One has a flaccid paralysis of both lower extremities after eight weeks. One has made a complete recovery. It would appear that the ideal treatment in the light of present knowledge and experience consists of: (1) Early puncture and withdrawal of cerebrospinal fluid; (2) Administration of adrenalin intraspinally; (3) Followed immediately with the introduction of immune serum or, in its absence, normal serum.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

HEART DISEASE IN THE EXPEDITIONARY FORCE IN FRANCE—VALVULAR CASES—DR. PARKINSON'S SUMMARY OF FORTY CASES OF DISORDERED ACTION OF THE HEART—"HEART STRAIN" AND "SOLDIER'S HEART."

London, August 5, 1916.

Dr. John Parkinson, temporary captain R. A. M. C., attached to the military hospital for heart cases, and the cardiac department of the London Hospital, has recorded the result of his inquiry into the conditions leading men on active service to report sick, with symptoms suggestive of heart disease. He based his inquiry on 90 cases passing through the casualty clearing station with the Expeditionary Force in France. Every patient sent to his wards from a field ambulance with a diagnosis of heart disease, from March, 1915, to January, 1916, is included in the inquiry without either selection or rejection, so that the series is consecutive. But the number seen gives no indication of the frequency of the cases or their proportion to the total sick. Absence of special means of investigation and the brief period of observation—usually 2 or 3 days—were disadvantages in the inquiry, but there was an advantage in that the men were seen very shortly after reporting sick. A detailed history of each patient was first obtained; notes on infections, recent or remote, followed by a statement of his capability of exertion at school and at work. The effects of training and campaigning were next noted and then the immediate cause for reporting sick. About an hour would be required to secure a satisfactory history, for the most part in the patient's own words, without leading questions. His general condition and temperament were first noted; then the position of the apex beat in the recumbent position, which served as some guide to the size of the heart; for its functional efficiency a fixed amount of exertion served as a test. In the 90 cases there were 22 in which other diseases were present. Of these 2 had acute and 3 chronic nephritis, 1 acute and 1 chronic bronchitis; one had enlarged thyroid and tachycardia; one had goiter without symptoms of thyroidism though complaining of a choking sensation when marching; three were for disordered heart action on account of syncope and 3 others for an unusual degree of sinus arrhythmia; the 7 others were considered examples of tuberculosis (pulmonary), arteriosclerosis, chronic alcoholism, immaturity, debility, epistaxis and lymphatic leukemia.

Among the 90 cases there was valvular disease in 28; 8 of these had mitral incompetence, 4 mitral stenosis, 8 aortic incompetence, 1 aortic stenosis, 2 acquired pulmonary stenosis (with rheumatic history, thrill over pulmonary area), 1 had aortic and

mitral incompetence and there were 2 patients with doubtful mitral stenosis. A case of thoracic aneurysm and one of dextrocardia are for convenience included in this series of 28.

In 16 cases there was a history of acute rheumatism; in 18 the chief symptom was shortness of breath; in 8 it was pain, but these had dyspnea as well. There was palpitation in half the cases; of 8 patients, 6 having aortic incompetence, complained of giddiness or faint feelings. Syncope had occurred in 1 case of aortic incompetence and in 1 of pulmonary stenosis. Great exhaustion on the march, with weakness of the legs on exertion, was complained of, in many cases before enlistment. A man of 40 had a two-and-fro (bellows) murmur without displacement of apex beat, and had served 16 months, including 6 at trench work; he had no symptoms and the incompetence was discovered at a chance examination.

The so-called soldiers' heart was present in 40 cases. These were men complaining of heart symptoms, especially breathlessness and precordial pain but in whom physical signs could not be found. In the army service they are classified as D. A. H. (disordered action of heart); in general medical literature they are often referred to as "soldier's heart." They are also at times spoken of as "irritable heart" and "heart strain," but the terms have little to recommend them. Captain Dr. Parkinson gives a careful summary of 40 cases, from which important conclusions can be deduced. Thus among soldiers in training or on active service a number come on the sick list for cardiac symptoms on exertion, but who have no physical signs of heart disease. They are the subjects of a cardiac disability which is manifested on the exertion required of a soldier, but this is not a specific disease and requires no such name as "soldiers' heart"; in fact it had in about half the cases been perceived before enlistment. The inefficiency may be a sequel of acute rheumatism, influenza or some other infection; so it may be due to myocardial changes due to age, especially in soldiers of 40 or more; or again to functional nervous disorder; or to limited cardiac efficiency, the patient having always been "short-winded"—maybe from an unrecognized infection in earlier years or defective physical training. A simple exertion test, as climbing a few steps, reproduces the symptoms and so gives information on the efficiency of the heart's function. Some degree of myocardial disease is present in numerous cases as seen in the persistence of the disability and the reaction to simple exertion tests. From this Dr. Parkinson concludes that the absence of abnormal physical signs in the heart of a soldier should not prevent his discharge from the army if, under training or on active service, he shows breathlessness and precordial pain whenever he undergoes exertion which is well borne by his fellows.

Gonorrhea in Women.—F. McCann states that when a man becomes infected with the gonococcus he soon becomes aware of its presence. A woman, accustomed to having a leucorrheal discharge of varying severity and various premenstrual and menstrual pains, may never be aware of the acute stage of a gonococcal infection. Moreover, a woman infected by a man with chronic gonorrhea usually has a subacute infection. Salpingitis, although occurring some weeks or even months after infection, may be met with quite early in the disease and cause symptoms suggesting an acute peritonitis.—*Practitioner.*

7. Auricular Standstill: An Unusual Effect of Digitalis on the Heart, with Special Reference to the Electrocardiogram. Paul D. White.

2. Fractures of the Lower End of the Humerus.—W. E. Ladd presents a study of 45 cases from the Children's Hospital in which the records are complete, the skiagrams satisfactory, and end results have been secured. In general, the method of treatment followed had been reduction by manipulation only and immobilization in the position of acute flexion. In a small number open operation has been resorted to, or a special variation in the position of immobilization, as indicated by the direction of the displacement of the fragments. For restoration of function, massage and passive motion have not been employed, but active motion has been relied upon entirely. There were 25 cases of supracondylar fracture which gave a total of 84 per cent. perfect results, with a probability that 92 per cent. of the cases will be eventually perfect. All of these cases in which there was slight displacement or no displacement gave perfect results. For displacements which are irreducible operative reduction is practiced immediately after the injury before swellnig has taken place or a few days later when the swelling has had time to subside. In general the practice pursued was that of Ashurst and Treves and his colleagues. After a careful study of the work of Neuhof and Wolf, the author states that he does not believe that their conclusions are correctly drawn, nor that their results justify the adoption of early passive motion and massage as valuable treatment. The results of operative treatment in a few selected cases in their series to some extent justifies its employment. It is found that from three widely separated clinics, cases treated upon general lines of similarity have yielded approximately 90 per cent. of perfect results, and hence one is justified in saying that a fracture of the lower end of the humerus in a child treated properly should result in a perfect arm in nine cases out of ten and a useful arm in practically every case.

5. A Suggestion as to the Prevention of Infantile Paralysis.—W. Stewart Whittemore refers to the work of Hektoen and Rappaport, which shows that kaolin is effective in removing bacteria from the nose and throat. His personal experience with the use of this agent in the treatment of infections of the nose and throat during the past year has been very gratifying and he suggests that it may possibly be effective in preventing the infection of children and adults with infantile paralysis. Powdered kaolin should be inflated into the nose and throat every two hours during the day. He says that only by the use of kaolin in a large number of cases in which there has been exposure to possible infection with poliomyelitis can it be determined whether it is of value or not.

6. Preoperative Roentgenological Examination in Cancer of the Breast.—John W. Lane points out that early recurrences and early postoperative deaths in cancer of the breast are often due to the performance of an efficient operation upon badly selected and already hopeless cases and that such occurrences bring the

operation into disrepute. During the past year he has made it his custom to subject every case of cancer or suspected cancer of the breast to a very complete roentgenological examination. It has been possible by this means to demonstrate metastases in the mediastinum, in the femur, pelvis, spine, and humerus; but not as yet has he been able to demonstrate to his complete satisfaction a pleural dissemination. These cases were prevented from going to the operating table and were not subjected to needless surgery. The writer advocates a thorough roentgenological examination as a routine preoperative procedure in all cases of suspected cancer of the breast.

7. **Auricular Standstill: An Unusual Effect of Digitalis, with Especial Reference to the Electrocardiogram.**—Paul D. White reviews the usual ways in which digitalis may affect the human heart and electrocardiogram and calls attention to another effect which he has not seen described. That is the removal by digitalis of all evidence of auricular activity from the electrocardiogram and from the jugular pulse tracing. There is no evidence that the auricle is contracting at all. Against the possibility of an isoelectric P in Lead II is the absence of P in Leads I and III also, and the absence of *a* in the jugular pulse. Auricular fibrillation may be excluded by the entire absence of fibrillation, oscillations of the galvanometric string, and the perfectly regular ventricular rate. The atrioventricular node is probably giving rise to ventricular complexes, because their shape is that of normal complexes of supraventricular origin and they occur regularly. No deflections appear, suggesting that the atrioventricular node is also giving rise to auricular activity. In other words, there appears to be auricular standstill. Three cases have been found at the Massachusetts General Hospital in which this digitalis effect has been seen. All three showed definite evidence of auricular action in electrocardiogram and jugular pulse tracings after the effect of the digitalis intoxication had worn off; in all three the A-V conduction showed some delay during the recovery from the digitalis. In none of the three at the time of the disappearance of auricular activity was there any evidence of auricular fibrillation, ventricular escape, or complete atrioventricular rhythm.

9. Abnormal Labor. Solomon Wiener.

2. **Autotherapy in Poliomyelitis.**—Charles H. Duncan advises a trial of autotherapy in the treatment of poliomyelitis based on a personal experience with twelve cases in which this method of treatment seemed to influence the prognosis favorably. His suggestion is to withdraw a considerable amount of spinal fluid and inject a small portion of it into the muscles of the back. Autotherapy has proved effective in cerebrospinal meningitis and other toxic neuritides, and it is logical to conclude that it may be applicable to poliomyelitis. The writer also suggests that tests be made in treating tetanus and other toxic neuritides by the autotherapeutic method.

3. **The Control of Epidemics.**—Jacolyn Manning discusses the problem "What should be done in invasions like the present one of infantile paralysis?" and suggests that a competent pathologist and diagnostician should investigate the cause of death and the contributory cause of death in every case, and state these on the death certificate during the period of the plague. Where there is the slightest doubt of the cause of death a postmortem examination should be made of the central nervous system, brain, midbrain, and spinal cord, since this is the only way of determining with accuracy whether or not any person has been a victim of poliomyelitis. The list of diseases terminating in sudden death which may simulate poliomyelitis is quite extensive, including, in very young infants, gastroenteritis, bronchopneumonia, measles, and diphtheria; in adults, ptomaine poisoning, lockjaw, cerebral apoplexy, and heat stroke. A missed diagnosis and faulty death certificate in a fatal case of epidemic poliomyelitis endangers the community more than a frank case of paralysis. A point of value in handling an epidemic which kills by the thousands and cripples when it does not kill would be the interdiction of all public funerals in any city during the progress of an epidemic. There were 188 deaths of children under 5 years of age from diarrheal disease reported for the week ending August 5, 1916, in New York City. It would be interesting and might prove instructive to hold postmortem examinations for one week, with microscopic examinations in all fatal cases in which the death certificate stated gastroenteritis to be the cause of death.

5. **A Study of Drug Action.**—Thomas J. Mays states that sound is a force like heat, light, and electricity, and possesses the fundamental physical properties of motion, action, and reaction with which other physical forces are endowed and is amenable to the same therapeutic laws which obtain among the substances that he has considered in previous papers on drug action. In other words, he considers music a force, the elective action of which is confined to the field of the human emotions, and that it exerts a stimulant as well as a depressant action. He points out how these properties may be made available in the field of therapeutics. Generally speaking, the stimulant action of music lies within the bounds of the various major keys, which may be said to move in harmony with the various bodily forces; its depressant action, while not having an intense antagonism to the normal movement of the bodily forces, nevertheless sets up a sufficient interference with the latter to occasion a state of mental despondency. Major music is a tonic to the emotions which may be compared to a stimulant dose of strychnine or quinine, while minor music depresses emotional activity in a manner comparable to bromide or a sleeping potion. The apparent objections to this theory are discussed and the opinion expressed that music as an agent in the treatment of consumption has probably a stronger claim on the scientific attention of the medical profession than many of the remedies that are in use at the present time. Keeping in mind the undercurrent of tribulation and oppression that is nearly always present in the minds of those suffering from consumption, it would seem probable that by far the larger number of cases would receive benefit from various forms of major music.

7. **Radiotherapy in Chronic Arthritis.**—Ernest Zueblin reports a number of cases in which the ordinary antirheumatic remedies did not produce the desired therapeutic effects and in which radioactive substances, such as mesothorium, locally applied to the diseased joints produced a remarkable change in the subjective and objective symptoms of acute and chronic deforming arthritis. Not only is pain relieved by the local application of the radiating energy, but also the infiltration of the articular and periarticular structures becomes less noticeable, and a reduction of the synovial fluid and a gain in the active and passive motility are no-

ticed. The danger of ankylosis resulting from the immobility of the joints engendered by the pain can and should be overcome by radioactive treatment whenever the ordinary internal medication proves unsatisfactory. Between radium, mesothorium, and magnesium sulphate there seems to exist a physical similarity which appears to be one of quantity rather than quality, and which may help to explain the similar therapeutic results obtained by the latter, though the rapid and more lasting effect must be expected from the more radioactive and fresh preparations.

8. **Toluol.**—Leverett Dale Bristol discusses the value of heat and various chemicals in the sterilization of vaccines made from nonsporogenous Gram negative bacteria, and emphasizes the fact that if enzymes and toxins are to retain their full strength to stimulate the formation of antienzymes and antitoxins the heat must be used very carefully or not at all in killing bacteria for vaccines. He suggests the following method of sterilizing vaccines by toluol: When a sufficient growth of a pure culture of bacteria has taken place upon the slant surface of plain agar medium, the toluol is run into the tube so that the entire surface of the medium containing the bacteria is covered. As a rule most of the Gram negative nonsporogenous bacteria will be killed in twenty-four hours. The toluol is then poured off to be used on other cultures, and the agar slants containing the killed cultures are replaced in the incubator for a short time to complete the evaporation of the toluol. Subcultures are then made to control the sterility of the vaccines, after which sterile salt solution is added and the dead culture carefully scraped off the medium into suspension in salt solution. If the toluol has not had too long an influence the bacteria retain their size, shape, and staining qualities.

1. **The Teaching of Dermatology.**—Howard Morrow comments on the tendency in a number of medical schools to place dermatology in the elective group of the curriculum and in others the tendency to decrease the number of required hours, thus conforming too closely to the minimum amount of time allotted by the schedule of the Association of American Medical Colleges, namely, forty-five hours. He says that if the student intends to become a general practitioner, to confine his interest to special branches, or to enter public health work, a course in dermatology and syphilography extending over at least sixty hours is absolutely essential. It is certainly unwise to graduate a student who cannot differentiate syphilitic lesions from those of a similar type, and who cannot recognize the mild form of variola and other exanthems. General practitioners should be able to recognize and treat ordinary impetigo and typical scabies. In the teaching of dermatology, lantern slides, colored photographs microscopy, and clinical demonstrations should be utilized. The advantage of having a serologic department connected with the department of dermatology cannot be overestimated. Modern investigation and research in dermatology indicate that there are many dermatoses associated with internal pathological conditions. This fact emphasizes the importance of treating patients with obscure cutaneous eruptions in a hospital where they can be studied from all phases by many physicians and observed by advanced students. By this method, cases in which the etiology cannot be ascertained will have the advantage of study by the dermatologist, pathologist, chemist, and the physician doing internal medicine, and in this collaboration rests the future in the study and development and teaching of dermatology.

7. **A Plea for the Prevention of Deformities in the Healing of Burns.** — Charles A. Parker recommends a treatment for burns of the so-called third degree and holds that however extensive such burns may be, so long as they are compatible with life, healing may and should be obtained without deformity and with good function. The treatment consists in the application of movable plaster casts in the early stages of healing, before contractures occur, over the proper dressing of the burn. The elbow, wrist, and fingers should be kept extended. The hip and knee should be extended with the foot at right angles to the axis of the limb, and the toes extended. For burns of the axillary region the arm should be maintained in an abducted position. In burns of the front and sides of the neck the chin must be kept high. The cast can be removed daily, the wounds dressed, and the cast immediately replaced during the whole process of healing. In dressing the wound after all sloughs have separated, ribbons of adhesive plaster are applied directly on the wound and extending some distance beyond the margins for attachment to the normal skin. The ribbons are usually placed at the margins of the burned area first and then laid on in parallel strips slightly overlapping each other until the whole region is covered. The adhesive plaster is changed two or three times a week, or whenever it becomes loosened from the healthy skin. Owing to its permeability it furnishes an ideal condition for healing and is much more efficient than a scab over large areas. Over the adhesive plaster a dressing of dry gauze is placed, which is usually changed daily. The changing of both the adhesive plaster and the gauze is painless.

8. **Sheet Rubber Superior to Gauze Sponges in Abdominal Operations.** — John W. Keefe. (See MEDICAL RECORD, July 8, 1916, page 86.)

9. **Localized Osteospondylitis.** — Willis C. Campbell reports four cases in which certain local changes were found in the vertebra which appeared to be analogous to nonarticular osteoarthritis and for which he has employed the term osteospondylitis. This process, of which he finds no accurate description in the literature, is decidedly local and seems to be an affection of one intervertebral disk. The roentgenogram shows crescent-shaped lamellæ of bone which are thrown from the

body of one vertebra to its adjacent fellow and may completely encapsulate the disk, producing solid external fixation of two vertebræ or only a part of the circumference may be involved. In some, the bony ridge may be incomplete and connected by only one extremity to the vertebral body, and at times there may be no apparent union of either extremity to the bodies. Similar anomalies may be seen in other spinal affections, especially spondylitis deformans, but always multiple and often involving the entire spine. In all four of the cases reported the affection was in the lumbar region. The etiology is probably the same as in monoarticular osteoarthritis. Three of the cases were relieved by simple orthopedic procedures, as no focal infections could be found. These cases are reported because the differential diagnosis of spinal lesions by the roentgenogram is very meagerly considered in the literature, few text-books mentioning local manifestations aside from those due to traumatism or tuberculosis.

10. **The Value of the Wassermann Test in Pregnancy.**—Frederick Howard Falls and Josiah J. Moore. (See MEDICAL RECORD, June 17, 1916, page 1114.)

11. **A Study of an Epidemic of Fourteen Cases of Trichinosis with Cures by Serum Therapy.**—Benjamin F. Salzer makes this preliminary communication, based on a study of 14 cases of trichinosis, in which the patients were admitted to the wards of St. Joseph's Hospital, Far Rockaway, N. Y. In the course of these studies he has confirmed the following findings of others: 1. The Kernig reaction was present in all the cases. 2. Edema of the face occurred in all the cases. 3. Edema of the lower extremities occurred in six cases. 4. The reflexes in the lower extremities were abolished in all the cases and are still absent now (six months having elapsed since the cases first came under observation). 5. Trichinæ were found in the blood in nine cases of the fourteen. 6. Trichinæ were readily found in the cerebrospinal fluid in eight of the fourteen cases. In addition to these observations he has found that the diazo reaction was in direct proportion to the degree of eosinophilia. The leucocytosis diminished as the eosinophilia increased. The blood coagulation time is markedly prolonged in trichinosis. In one case of trichinosis in a child three years of age trichinæ were still found in the cerebrospinal fluid three months after the clinical recovery. Trichinæ were not found in the urine in any case. They were not found in the uterus but were abundantly present in the placenta. They were present in large numbers in the milk of a nursing woman and were found in the piece of mammary gland excised. In two cases the duodenal tube was passed under control of the fluoroscope; in one of these, trichinæ were abundantly found. This patient was now suffering from cholecystitis. The feces were clay colored throughout the disease in every case; this was probably due to the reduction of bilirubin by living trichinæ. Trichinæ were present in the stools of all the cases throughout the disease and in three cases in which studies were carried on after recovery. The author relates a number of observations made on animals and states that the use of serum from human patients who recovered removed the eosinophilia persisting after recovery in man or animals within forty-eight hours. The injection of normal serum had no therapeutic value in trichinosis in man or animals; the same is true of salvarsanized serum and salt solution. In animals the injection of convalescent serum gives an almost complete prophylactic result. In two cases of trichinosis in the very active stage of the disease the use of immune serum proved to be of remarkable curative value. In twenty-four rabbits suffering from the disease, experimentally produced, the immune serum had a curative effect within twenty-four hours.

13. **A Note on the Serum Treatment of Poliomyelitis.**—Simon Flexner reviews the experiments on monkeys which have formed the basis for the serum treatment of poliomyelitis, refers to Netter's results with the serum treatment in a series of 35 cases of the disease, and says the serum injections are usually given subdurally as early after the appearance and recognition of the symptoms of poliomyelitis as possible. The dose of the serum must be sterile, not necessarily activated, and should be determined by the age of the patient and the amount of serum available. Probably doses ranging from 5 to 20 c.c. will be suitable, the injections to be repeated several times at twenty-four hour intervals, according to clinical conditions and indications. Since the immune substances have been found to persist in the blood for many years, it is probable that persons who have passed through an attack of poliomyelitis many years earlier may be utilized as sources of the serum; reasoning from analogy it would probably be advantageous to prefer persons whose attack was less remote, so as to insure as high concentration of the immune bodies as possible. The conditions surrounding the injection of the serum into the meninges are identical with those observed in the analogous case of epidemic meningitis. The effects of the immune serum should be sought in the prevention or minimization of the paralysis when employed in the preparalytic stages, and the arrest of its extension when used in progressing paralytic conditions.

1. **Observations on Fifty Laparotomies Performed for Gunshot Wounds of the Abdomen.**—G. H. Stevenson and C. Mackenzie present a synopsis of these 50 cases, of which 17 recovered and 33 died. The cause of death in the fatal cases was as follows: general peritonitis, 10 cases; hemorrhage and shock, 19; lung conditions, 2 cases, and secondary hemorrhage from the kidney in one case and sloughing of the gut in one case. Since the beginning of the war the opinion with reference to the expectant treatment of abdominal wounds has undergone a change and completely altered the outlook in such cases. Patients are operated on as quickly as possible. It is wrong to wait, no matter how bad the patient may appear, as so often in such cases hemorrhage and infection are progressing. Even though no pulse can be felt, an operation is not thereby contraindicated, as it gives the last possible chance of recovery. Many of the patients in this series were operated on within five or six hours of their being wounded, though many others did not reach the hospital for twelve to twenty-four hours. Regarding the question of whether a man will stand an operation or not, they took the view that, if intraperitoneal perforation of the gut is present he will almost certainly die if not operated upon, and that it is right to give him the chance, even though it be only one in a thousand. The technique used in these operations differs little from

that in the similar operations of civil practice, end to end anastomosis being the usual method when resection is necessary, except when several feet of the gut have to be removed, when the lateral anastomosis is employed, as this is undoubtedly stronger. Where suture is possible, suture in the transverse axis is preferable to the longitudinal in lesions of the small intestine. The writers have found pituitrin a most valuable drug in the after-treatment of abdominal cases. In a recent article it is stated that it is not so usual in gunshot wounds of the bowel for the gut to be completely divided; in the present series this is a comparatively common occurrence.

2. On the Advantage of Using Broth Containing Trypsin in Making Blood Cultures.—S. R. Douglas and L. Colebrook have confirmed the findings of Wright and his fellow workers, which showed that when, by mixture with trypsin, the antitryptic power of the blood is neutralized, the blood loses its power of clotting and also its bactericidal properties. They state that these are precisely the changes which it is desirable to bring about when attempting to cultivate pathogenic microorganisms from the circulating blood. A series of blood cultures performed in duplicate with trypsin broth and simple broth has shown that the employment of trypsin in that procedure is clearly advantageous, the organisms having been in some cases recovered only in the trypsin tubes, while in other cases they were recovered earlier and more frequently in these than in the control tubes. It is probable that this method favors the cultivation of any microbe that may be present in the blood, and not especially one particular organism or group of organisms, as is the case with bile media; staphylococci, streptococci, paratyphoid bacilli, and anthrax bacilli, were readily isolated from blood by the use of trypsin broth. In order to be sure of neutralizing the antitryptic power of the inoculated blood it is recommended to employ broth containing not less than 5 per cent. of trypsin solution (compound solution of trypsin, Allen and Hanbury's) and to add not more than 1 c.c. of blood to each 5 c.c. tube of such broth. When blood has to be sent by post to a laboratory, undiluted trypsin solution may be added to the specimen of blood immediately on its withdrawal from the vein, in the proportion of 1 of trypsin to 4 of blood.

3. Treatment of Carriers of Amebic Dysentery.—H. H. Dale states that the problem in the treatment of entamebiasis in England during the past year has been that of freeing the chronic "carriers" from their infection. While experience in Egypt has led to the conclusion that a full course of 10 or 12 grains of emetine hydrochloride, given hypodermically, will practically always eradicate the infection, experience has shown that there is a not inconsiderable proportion of cases in which such a course of emetine treatment has led only to a temporary absence of cysts from the feces. Ten cases regarded as hopeless when treated by this method have been given a course of treatment with double iodide of emetine and bismuth with the result that six of these patients have shown six weeks' absence of cysts with daily examinations. Thirty to 36 grains of the double iodide of emetine and bismuth, equivalent to about 10 to 12 grains of emetine hydrochloride, has been regarded as a full course, and the daily dose has varied from 2 to 4 grains, given in capsules. The frequency of vomiting under this treatment is in no way comparable to that seen with the ipecacuanha treatment, and there is no need to adopt the precautionary measures to avoid vomiting which the latter treatment entails.

4. A Note on the Necessity for Prolonged Treatment in Cases of Infantile Paralysis.—Francis Hernaman-Johnson believes that much of our treatment of the weakness and deformity which may result from an attack of infantile paralysis fails owing to lack of proper following-up. He reports an illustrative case that showed no improvement for over two years and then under careful orthopedic treatment and supervision a very marked improvement ensued. He states that the therapeutic lessons which have been learned in connection with infantile paralysis are of special interest because they are equally applicable in dealing with war injuries to nerves and muscles. The following three lessons should always be kept in mind: 1. A muscle which is chronically overstretched cannot recover. It must be relaxed by means of a suitable splint. This principle was insisted on by Robert Jones many years ago, and its importance cannot be over-emphasized. 2. When such a muscle responds moderately well to faradism—or, in more modern terms, to the small or medium capacities of the Lewis Jones instrument—its recovery will be greatly hastened (and in some cases even determined) by daily rhythmical electrical stimulation. The relaxed position must, however, be maintained throughout. 3. Exercise, whether voluntary or electrically provoked, must never be carried to the point of fatigue. The contraction of a muscle should be not less vigorous—with the same stimulus—at the end of a sitting than at its commencement. It is better that recovery should be delayed by over-caution than that it should be made impossible by excess of zeal.

1. **Two Hundred Consecutive Hysterectomies for Fibroids Attended with Recovery.**—John Bland-Sutton has removed the uterus for fibroids in more than 2000 women. In the Middlesex Hospital, in 1892, three women had the uterus removed for troublesome fibroids; two died in consequence of the operation. In 1912, there were seventy-one abdominal hysterectomies performed in the hospital and all recovered, showing a great improvement in twenty years. Of the last 200 cases of hysterectomy for this disease that the writer has performed in this hospital all recovered. Among these 200 hysterectomies 188 were subtotal. During the period covered by these 200 cases hysterectomy has been performed in the writer's ward for adenomyoma, fibrosis uteri, cancer, septic infection, and for ovarian fibroids three times, and also four abdominal myectomies. All the patients recovered. These results have been obtained with a minimum use of antiseptics. Women with uterine fibroids who show signs of diabetes, exophthalmic goitre, cardiac disease, arterial sclerosis, and albuminuria are rarely submitted to operation. After describing the different varieties of fibroids the author ventures the following aphorisms: There are two things disquieting in diagnosis: 1. To distinguish between solid ovarian tumors and large subserous fibroids. 2. And between tubal swelling and uterine fibroids. Three foolish things are: 3. To give opinions on pelvic swellings without making a vaginal examination. 4. Or on hypogastric swellings without passing a catheter. 5. To remove fibroids without ex-

amining the woman's urine for sugar until she is comatose two or three days after the operation. Four things useful to know: 6. When a barren woman between 35 and 45 has retention of urine, it is almost certain that she has a fibroid in her womb. 7. A fibroid that suddenly becomes painful during pregnancy is probably in a state of red degeneration. The clinical signs simulate tubal pregnancy, axial rotation of an ovarian tumor, and acute infection of the appendix. 8. Errors in the differential diagnosis of fibroids and pregnancy are usually made before the beating of the fetal heart is audible. 9. A cancerous mass in the pelvic colon, in contact with the uterus, imitates the signs of a subserous fibroid. Four things that are wise: 10. When in doubt whether a big uterus in a young woman contains a child or a fibroid, wait for a month and re-examine the patient. 11. To remember that ovarian tumors give much trouble to pregnant and lying-in women, but fibroids are more deadly, for they are liable to become septic. 12. After the removal of a fibroid in the procreative period of life a woman is more liable to grow more fibroids than to conceive successfully. 13. To remember that uterine bleeding after the menopause, in a barren woman with a fibroid, often signifies the existence of cancer within the uterus.

2. **Some Notes on Trench Fever.**—T. Strethill Wright relates that among a large number of cases that came to them from the front there were thirty cases of a new type. They were characterized by a peculiar temperature chart, which showed a series of "spikes" occurring at more or less regular intervals, and separated by afebrile periods. The onset was generally sudden, the majority of the cases showing an initial period of pyrexia of two to three days, severe headache, and pain in the legs and small of the back. The pain so far as could be determined was invariably muscular. During the febrile paroxysms the other symptoms were always worse. The fever was accompanied by loss of appetite and coated tongue. Sweating was a common accompaniment of the sharp falls in temperature. The only other common symptoms was a tendency to constipation. Attempts to discover an organism to which the infection may be attributed have not as yet been rewarded with success. The examinations of the blood, feces, and urine, in a large number of cases were all negative as to evidence of typhoid or paratyphoid infection. The evidence shows that these were not atypical cases of enteric, but genuine cases of trench fever, and it may be definitely stated that the disease has every appearance of being a distinct clinical entity.

3. **The Pathogenicity of Giardia (Lamblia) Intestinalis to Men and to Experimental Animals.**—H. B. Fantham and Annie Porter present their personal evidence based on their observations of pure cases of lambliasis in man and of some experiments with human Lamblia on animals. They state that in both human and animal lambliasis stools, as well as at post-mortem examinations, erosion, and distortion of the intestinal epithelial cells occurred, owing to direct suctorial action of the flagellate Lamblia. Giardia (Lamblia) intestinalis is pathogenic to man, and is capable of producing diarrhea, which may be persistent or recurrent. The virulence of the parasite varies, and lambliasis occurs in tropical and non-tropical countries. The Lamblia cysts can remain infective for some time. Lambliasis occurs in rodents, especially rates and mice, and can be of human origin. Lambliasis may also be produced in cats. It is possible for such animals to serve as reservoirs of lambliasis, and by contaminating the food of man by their excrement to propagate lambliasis. Sufficient atttention has not been given to this method of infection in the trenches in the fighting area.

7. **The Duration of Bilharziosis in South Africa.**—F. G. Cawston says that, judging from the number of men who were infected with bilharziosis during the South African war and the number of these who are still receiving compensation from the army authorities, a study of the duration of the South African form of this infection is of great importance. He finds that the vast majority of persons in Natal who suffered from the affection some twenty or thirty years ago have by this time entirely grown out of the symptoms, and in a large number of these microscopic examination of the urine shows no evidence of the past infection. On these grounds a life insurance company can be recommended to accept an otherwise suitable applicant at the usual rates, provided the urine has shown no sign of blood or mucus for one year and has not contained any of the eggs for six months, so far as can be judged from occasional microscopic examinations. A number of those, however, who contracted the disease twenty or thirty years ago have suffered continually from its symptoms ever since, though they may not have been sufficiently severe to require continuous medical treatment. Several cases in which the disease has persisted are cited which lead to the conclusion that even if some of the remedies employed are effective in destroying the parasites in the blood stream and in diminishing the hematuria, the escape of the spine-pointed eggs which continues is too frequently associated with bacilluria and damage to the bladder wall to enable one to pronounce such a case as cured, even though it is exceptional to hear of cases which have died or whose lives have been shortened by bilharziosis.

La Presse Médicale.

July 24, 1916.

Differential Diagnosis Between Pulmonary Tuberculosis and Chronic Affections of the Nasal Fossæ.—Rist discusses protracted cough and other symptoms of intranasal origin which simulate tuberculosis of the lungs despite inability to find the bacillus and perfectly clear *x*-ray shadows. These patients may or may not present stethoscopic alterations in the thorax. It is not enough to tell them they are not tuberculous; some explanation must be found for the cough. The cardiovascular apparatus and kidneys should be examined. Mitral stenosis has simulated phthisis, by reason of associated cough and hemoptysis. Another condition which sometimes simulates tuberculosis is gastroptosis with gastric atony. These subjects emaciate and often cough after meals. The old rule holds good that whenever you cannot make a diagnosis, suspect tuberculosis. To exclude this gastric affection an *x*-ray following a bismuth meal is sufficient. Abortive Graves's disease is a third affection which can simulate consumption, especially if the thyroid and eyeball are not prominent. However, negative sputum and *x*-ray finds readily exclude tuberculosis. But there are numerous suspects which have none of the preceding affections, especially among the troops. By the way, it is singular that in the routine examination for suspected tuberculosis, the nasal passages are seldom included. This is a great error when we consider the number and variety of lesions which are of common occurrence in the latter, and the symptoms to which they give rise, including cough and hemoptysis. It is true that subjects with narrow fossæ, spurs, etc., soon learn to adapt themselves to the disturbed respiration. The author, however, knows of a rhinologist who was believed to be in consumption who had nothing worse than chronic purulent rhinitis. Patients of this class take cold

frequently, and every morning must clear the upper respiratory tract of tenacious, often bloody mucopus which is often present in large quantities. Every Spring their conditions seem aggravated and they believe themselves affected with some serious intrathoracic infection. Other patients have atrophic rhinitis and rejoice in dry, clear passages. They "never need handkerchiefs." Yet these subjects are mouth breathers, because one or both nostrils is obstructed. All such subjects may often be recognized at a glance by the large, thin, curved nose, sometimes deflected to one side, which suggests unerringly congenital narrowness of the nasal passages. The contour of the nostrils also readily indicates the same condition. A thick root of the nose suggests hypertrophy of the middle turbinals. When these subjects speak the voice also betrays them (rhinolalia of a special type). As is well known subjects with chronic rhinitis are also hoarse. The cough may be dry or moist, and aside from sputum which is merely streaked with blood, we may see at times free blood from rupture of varicosities in the throat. Some of these patients also suffer with bronchitis with slight temperature rise which, of course, points all the more to phthisis—even to the stage of softening. How is this pseudotuberculosis produced? We have plainly to do with a nasal insufficiency with "false passage" (mouth breathing). As is well known certain authors now contend that mouth breathing by causing slight flatness at the apices from lack of inflation is the most puissant cause of clinical pseudotuberculosis in its initial stage. Lemoine holds this view in moderation, while Krönig pushes it to extremes in speaking of a sclerosing atelectasis. The author describes at great length his views of spreading infection from some focus in the nose, which slowly involves some of the sinuses, cause polypi, tonsillitis, the "closed follicles" of the pharynx (which are mistakenly cauterized by rhinologists), chronic catarrhal laryngitis, etc. In other words, a spreading infection is fastened upon a noninfectious condition—which is simply one of malformation. The original nasal insufficiency is of course greatly aggravated. A bronchitis represents a downward extension of the process. As a matter of fact but little bronchitis is primary. True primary bronchitis is simply essential asthma. To combat the entire chronic infection we must begin at the parent spot—the septal spur, hypertrophied turbinate, the chronic sinusitis. The result will often be surprising. The "tuberculous" subject is suddenly cured.

La Presse Médicale.

August 3, 1916.

Glycuronuria and Its Variations.—Gautier refers to the study of Roger and Chiray of the presence of glycuronic acid in the urine. As a product of the hepatic cell, it was investigated in connection with diabetes, hepatic cirhosis and retention icterus; also in pneumonia and cancer. The author has gone over the ground, and his results tend to confirm the claims of Roger. The test used by Grimbert and Bermier is preferred to that employed by Roger. The urine is treated mercuric acetate and the filtrate heated with naphthoresorcin and chlorhydric acid. After cooling it is shaken up with an equal volume of ether. If the result is positive a blue violet color appears. If the result is negative there is either no color change or one of yellowish brown. According to Roger, the human urine always contains a little glycurnic acid. Its percentage varies with the diet. It is relatively large in meat eaters and small in those on a vegetable or milk regimen, and after fasting. Ingestion of a little camphor will in such cases cause the percentage to rise. In hepatic insufficiency the acid disappears wholly from the urine when the prognosis is fatal, and is a good measure of hepatic efficiency, the amount dwindling with the degree of insufficiency. If there is some doubt as to the result, Roger uses an alimentary reinforcement in giving 1 gram of camphor. If the result is then negative, the liver is hopelessly compromised. The author has tested 200 subjects, including the sound and diseased. Camphor will not increase the amount present in the urine of the healthy (the tested subject must be on a standard diet). Given to those with hepatic disease variable results follow. In diabetes the result is always negative. In hepatic cirhose it may at first promote the elimination of the acid, but not in the advanced case. Roger found the maximum per cent. of acid in a case of acute lysol poisoning. On the next day no acid appeared in the urine, but this default lasted but a short time. This overproduction of acid in the presence of camphor and lysol suggests that an antitoxic activity is involved, either by combination or elimination. In absence of acid in the urine of diabetics the sugar seems to be in no wise concerned. In Laennec's cirhosis of the liver the acid which nearly vanishes in the presence of ascites increases in per cent. after tapping. In cardiac liver results were inconsistent, but the presence or absence of the acid has a marked prognostic value. In cancer of the liver suppression of acid in the urine means an early death, according to Roger, who indeed here includes cancer in all localities. The author's results are quite opposed to this teaching. In conclusion he expresses the opinion that the research into glycuronuria will yield most valuable results in diagnosis and prognosis.

La Bulletin Médical.

August 5, 1916.

Virilism and Inversion of Sexual Characters.—Blanchard considers this subject from the special viewpoint of the activities of the interstitial tissues of the generative glands. By virilism he refers of course to acquired made characteristics in the female. Hippocrates relates two cases of virilistic transformation in women named Phoetusa and Namyxia. Ambroise Paré described certain degenerate women whom he termed hommasses (viragos) who, in losing their feminine somatic characteristics, assumed those of men, becoming also robust and bold. He ascribed these changes to suppression of the menses. Apert was the first to advance a scientific explanation of acquired virilism, viz.: the presence of lesions of the suprarenal glands. It was not until later that changes in the sexual glands were held to be responsible, although these changes were alleged to be secondary to those in the suprarenals. Tuffier's celebrated case of suprarenal virilism reported in 1914 left no doubt as to the nature of at least one form of virilism. The author, who is a zöologist, states that analogous behavior is seen in certain birds. As far back as John Hunter attention was attracted to the assumption by elderly female birds of male plumage. Hunter regarded the phenomenon as teratological. The Germans have described such behavior under the term virilescence. The pheasant seems especially disposed to this affection, the transformation, however, being incomplete. The altered hens do not cease to lay. The theory advanced of ovarian origin seems to have little formation in fact. This virilescence has been noted in at least twenty-six species of bird belonging to four orders. All barnyard fowls seem to be included. Mammals are also subject to virilistic change, but the subject has received but scant attention. As in birds the changes are restricted to the tegumentary structures.

Insurance Medicine.

THE FUTURE OF INSURANCE MEDICINE.

In the issue of the Medical Record for August 12 there is a brief but very interesting article by H. E. MacDonald on the probable future evolution of insurance medicine. He shows very clearly that those who need the insurance most, those who are physically under par, are the very ones who find insurance hardest to get. The perfectly well find it easy to obtain but do not need it so much and often do not want it at all. He goes on to predict that in the future the insurance companies will accept all or nearly all risks and will base the rates in the individual case upon the prognosis offered by the examining physician. He continues: "Suppose an insurance company decide to conduct their business in this way. They will hold their examination in prognosis after the graduation of a class in a medical college. Those who pass will be appointed examiners whose duty it will be to examine insurance prospects *for a small fee or nothing* (italics ours). In doing this they will immediately have a practice, unremunerative it is true, but it will grow into a paying practice which will be along the line of preventive medicine, which will be the medicine of the future and which will be ushered in immediately by this plan of making life-insurance examinations."

It is in this part of his article that we wish to register our objection to Dr. MacDonald's plan. One of the faulty points of the insurance scheme as it is carried out at the present time is the inadequate fee which is paid, in certain sections and by certain companies, for examinations. There is nothing more true than the old saying that we get what we pay for and no more. The examination is only too often conducted in a hasty and inadequate manner so that it is the belief of many men in insurance medicine that they would do as well without physicians as with them. An experienced man, a good judge of his fellow men, and a keen observer would be able probably to pass the applicants at a glance with as good results as are obtained by the young doctor who does two or three hundred examinations a month at a dollar a head and in the interval attempts to build up his practice so that he may be able to quit the insurance business which he considers pot-boiling and of a deadly monotony. It is very generally admitted that accurate prognosis requires much more experience and keen observation than does the average diagnosis and yet it is proposed that this service be carried on by very recent graduates "for a small fee or nothing." The lure held out that "it will grow into a paying practice" is liable to prove a disappointment to those who try it. Most applicants who are already ill will have their own physicians and the young examiner will find that what little income he may be able to obtain will be eaten up in carfares while getting about to do his free examinations. It is a notorious fact that of all men, physicians do the greatest amount of work for nothing and, in consequence, their good nature is abused to a shameful degree. Let us register an earnest protest against any movement which aims to increase the amount of free work which is to be contributed by our ill-treated profession. We are happy to give of our time and labor to benefit our fellow man so far as we are able, but in return for that the least which we can expect is a living wage and such consideration as will enable us to maintain our self-respect.

Diseases of the Lungs, Liver, Pancreas, and Kidneys in Relation to Obesity.—Dr. F. Parkes Webber, in a paper read before the Assurance Medical Society in London, concerning diseases in relation to obesity, said that emphysema of the lungs with progressive dilatation of the right side of the heart and other results might be at first masked by obesity. Of great importance was the auscultation of the infrascapular regions for the more or less permanent crepitation which showed the presence of chronic catarrh or chronic edema of the base of one or both lungs. Pulmonary tuberculosis was, of course, generally associated with underweight rather than overweight, but there were exceptions, and old quiescent or obsolete pulmonary tuberculosis might, partly as a result of methods of treatment, occasionally be associated with a plethoric type of corpulence. It was a well-known trusim to say that the detection of cholelithiasis or nephrolithiasis might be rendered more difficult by the presence of obesity. Cholelithiasis was acknowledged to be relatively frequent among fat persons, rather more so in women than in men. Obesity might sometimes draw the examiner's attention away, and so in a sense, mask the presence of chronic nephritis, especially contracted granular kidneys, notably so if the urine only intermittently contained albumin, and even then in mere traces. Examination of the centrifuge sediment of the urine for tube-casts might be of some use, but it must be remembered that one or two hyaline or even granular casts might occasionally be found in the urine of practically healthy persons by the help of the centrifugal machine. Estimation of the brachial systolic blood-pressure might likewise aid in the diagnosis. Occasionally an ophthalmoscopic examination in such cases might reveal the presence of unsuspected retinal changes. In regard to the pancreas, one might remember that the subjects of acute hemorrhagic pancreatitis were not rarely corpulent individuals, or individuals who had been addicted to alcohol.

The Personal History.—Dr. W. A. Boyce says the personal history is very important, and a local examiner should never disregard a history of previous sickness. An applicant might say he had been treated by a physician in the adjoining town for "biliousness," when many times it was for syphilis, appendicitis, gallstones, or some other disease that would have quite an influence on his mortality. Inquiry should be made, and date, duration, and name and address of the attending physician should be given; also the abdomen should be palpated and other examinations made and details given of the findings.—*Texas State Journal.*

"Accidental Means."—In an action on an accident policy, it appeared that the plaintiff attended a football game on a cool day when the ground was damp, and contracted a cold, resulting in lumbago. After medical treatment and the debility resulting from a purgative, and while lying in bed, he had a paper brought, reached for it, and raised it suddenly above his head, when his strong blood pressure caused a rupture of the retina, destroying the sight of one eye. It was held he could not recover on a policy insuring him against bodily injury through "accidental means," since, while the result was not foreseen, the cause producing the result was not accidental, but an ordinary natural movement, executed as intended.—Stone v. Fidelity & Casualty Co. of New York, Tennessee Supreme Court, 182 S. W. 252.

Book Reviews.

CLEFT PALATE AND HARE LIP. By Sir W. ARBUTHNOT LANE, Bart., M.S., F.R.C.S., Senior Surgeon to Guy's Hospital, and Emeritus Surgeon to the Hospital for Sick Children, Great Ormond Street. Third Edition, 102 pages, with 58 illustrations and diagrams. Price, $4.00. London: Adlard & Son. Chicago: Chicago Medical Book Company. 1916.

LANE'S own contribution to this work takes up about 60 pages, of which about half is devoted to a statement of his views regarding the factors that influence the growth of the nasopharynx and of the mouth and of the bones that surround those cavities. He then propounds the following questions regarding cleft palate: "What is the best age for operation? (2) What is the best method of performing the operation? (3) How and when can any complication such as harelip be met to the greatest advantage?" From Lane's answers to these questions we learn that the best time for operation upon cleft palate is the day of birth or as soon after that as possible; that the best method of performing the operation is Lane's method, which is briefly described and is illustrated by a number of rather occult diagrams and which is to be performed with instruments devised by Lane "to replace the clumsy instruments originally in use;" and that if, besides a cleft of the hard and soft palate, the lip is defective on one or both sides, two courses are open to the operator—if the closure of the cleft in the lip does not interfere with the free passage of air through the nose the clefts in the lip and palate may be closed simultaoneously, but if the cleft in the lip is very extensive and if its closure will interfere with the free passage of air through the nares the lip and hard palate may be closed in the first instance, the cleft in the soft palate being dealt with later.

Mr. Cortlandt MacMahon contributes 10 pages on Speech Training, and Mr. W. Warwick James, 30 pages on Dental Treatment of Cleft Palate.

THE CLINICS OF JOHN B. MURPHY, AT MERCY HOSPITAL, CHICAGO. Vol. V, Number I. Octavo of 194 pages, with 32 illustrations. Published bi-monthly. Price per year, cloth, $12.00; paper, $8.00. Philadelphia and London: W. B. Saunders Company. 1916.

IN this number of the Clinics we find about one-fourth of the book devoted to six clinical cases that are of interest to the general surgeon; while the other three-fourths is made up of the seemingly inevitable and unending bone and joint material. This might well be called an orthopedic number; for it is of comparatively little interest to those not specializing in bone and joint work. From the ordinary subscriber's point of view we should say that this is about the poorest number of the Clinics that has yet appeared.

LATERAL CURVATURE OF THE SPINE AND ROUND SHOULDERS. By ROBERT W. LOVETT, M.D., Boston, John B. and Buckmeister Brown Professor of Orthopedic Surgery, Harvard Medical School; Surgeon to the Children's Hospital, Boston; Surgeon-in-Chief to the Massachusetts Hospital School, Camden; Consulting Orthopedic Surgeon to the Boston Dispensary; Member of the American Orthopedic Association; Corresponding Member of the Royal Society of Physicians, Budapest; Korrespondierendes mitglied der Deutschen Gesellschaft für Orthopädische Chirurgie, Socio della Societa Italiana di Ortopedia. Third edition, revised and enlarged; with 180 illustrations. Price, $1.75. Philadelphia: P. Blakiston's Son & Co. 1916.

THE third edition of Dr. Lovett's Lateral Curvature of the Spine contains an interesting added chapter on the History of Scoliosis. The chapter on treatment has been expanded and changed where Dr. Lovett's experience has given indication. The book is an excellent one and a new edition will be welcomed.

A MANUAL OF PRACTICAL NURSERY. Prepared for the Washington University Training School for Nurses in the Barnes and St. Louis Children's Hospitals. Edited by HELEN LILLIAN BRIDGE, B.S., R.N., Assistant Superintendent and Instructor of Nurses, Washington University Training School for Nurses, St. Louis. Price, $1.00. St. Louis: C. V. Mosby Company. 1916.

MISS BRIDGE'S manual should be very helpful to nurses in training. It is not a textbook, but gives such information as the nurse must have during her actual time on the ward. Requisites for various treatments are given and after each group a note stating the length of treatment or any special warning which may be necessary. Routines on surgical, gynecological and obstetrical sources are given, typhoid routine, routine for admission of patients.

There is an inset leaf between each two pages, so that variations can be noted and the book adapted to the use of every training school. The book will help a nurse as a constant check until the details of her work have become part of herself.

VENEREAL DISEASES, A MANUAL FOR STUDENTS AND PRACTITIONERS. By JAMES R. HAYDEN, M.D., F.A.C.S., Professor of Urology at the College of Physicians and Surgeons, Columbia University, New York; Visiting Genito-Urinary Surgeon to Bellevue Hospital; Consulting Genito-Urinary Surgeon to St. Joseph's Hospital, Yonkers, New York. Fourth edition, thoroughly revised. Illustrated with 133 engravings. Philadelphia and New York: Lea and Febiger. 1916.

THE author presents his fourth edition in more attractive garb by arranging his text in chapter form, by additional illustrations and by bringing the treatment of syphilis up to date. Condensed as it must be for students' use, the treatment of gonorrhea, urethral stricture, and syphilis are clearly and carefully written. Among other praiseworthy features is the advice to use the inunction method of mercurial administration in the treatment of syphilis. In view of the fact that this book is primarily intended for senior medical students and that the teachings in this period of a medical career are most lasting, the author wisely avoids theories, debatable therapeutic procedures, and in general holds his course to "the middle of the road."

DIAGNOSE UND THERAPIE DER GONORRHOE BEIM MANNE. Von Sanitätsrat Dr. S. JESSNER, Königsberg i. Pr. Zweite verbesserte Auflage. Preis 3.50 Mk. Würzburg: Verlag von Curt Kabitzsch. 1916.

WHOEVER enjoys the recitation of facts couched in beautiful language should read this book. As a scientific treatise on a common disease, much is lacking. The author arranges his second edition in the orthodox manner, beginning with the anatomy of the region and ending with the treatment of gonorrheal sequelæ. In the course of these chapters the reviewer encounters some untenable positions and unforgivable omissions. For example, he objects to urethral dilatations with modern dilators because their use requires much practice and much time is consumed in administering the treatment, the instruments are costly and are expensive additions to the physician's armamentarium, and because he can accomplish the same results with simpler methods. Sic transit Oberlander. The operation for rapid relief and cure of acute gonorrheal epididymitis as developed by an American surgeon is not mentioned, although it is universally accepted by urologists as the most modern and most conservative treatment. The book is not typically Teutonic in thoroughness, nor does it bear the marks of a labor of love. Likewise, it is devoid of illustrations.

THE PRINCIPLES AND PRACTICE OF PERIMETRY. By LUTHER C. PETER, A.M., M.D., F.A.C.S. Associate Professor of Ophthalmology, Philadelphia Polyclinic and College for Graduates in Medicine; Ophthalmologist to the Rush Hospital for Consumption and Allied Diseases. Illustrated with 119 Engravings. Price, $2.50. Philadelphia and New York: Lea & Febiger, 1916.

THE subject of perimetry is one that should enlist the very careful consideration of every practitioner of ophthalmology. The information obtained by the intelligent and thorough study of fields of vision is of very great importance as a means of diagnosis and of prognosis. The author of this work has presented the subject in a very attractive and practical manner.

Part I is devoted to a description of the normal field of vision and the various factors that influence its extent. Part II describes the methods employed in perimetry. Part III is concerned with the anatomy and physiology of the visual tract. Part IV treats of the changes in form of the fields for form and colors due to disease. Part V is devoted to a description of the fields of vision as they are affected by special diseased conditions. Part VI describes the changes in the fields of vision due to "functional" nervous disease. An appendix treats briefly on anomalies of the fields, due to loss of parallelism in visual axes and of the defects due to the presence of foreign bodies. A bibliography and index follow. The work is well adapted to the uses of the student.

Society Reports.

AMERICAN PEDIATRIC SOCIETY.

Twentieth Annual Meeting, Held in Washington, D. C., May 8, 9, and 10, 1916.

(Special Report to the MEDICAL RECORD.)

THE PRESIDENT, DR. ROWLAND G. FREEMAN, NEW YORK CITY, IN THE CHAIR.

Presidential Address.—Dr. ROWLAND GODFREY FREEMAN of New York said there was an agent of wonderful power and value to the pediatrician, the use and action of which was little appreciated, namely, fresh air. By fresh air as a therapeutic agent he meant moving and cool out-of-door air. This stimulated the appetite, induced quiet sleep, brought color to the cheeks, and increased the resistance of the organism to infection. The claim that fresh, cool air raised materially the blood pressure had not been confirmed by subsequent investigations, and they seemed to be driven to the position that the favorable action of fresh air on the organism was due to the absence of the deteriorating effects of closed rooms. In the fresh air the body had the advantage of normal conditions. The idea that air which had been breathed by other people was unhealthy probably arose from the unpleasant odor of closed and crowded rooms, and from symptoms elicited by extremes of this sort. The symptoms produced by closed places were depression, headache, thirst and difficult breathing and the elements producing these symptoms were supposed to be a diminution of the oxygen and an increase in the carbon dioxide, with the possible appearance in such an atmosphere of a really poisonous product from the expired air. Experiments, however, for the most part discredited this theory. The amount of oxygen in crowded, closed rooms was not depleted to a danger point, nor is the amount of carbon dioxide increased to such a point. Efforts to find a poisonous element in such air had been made from time to time with negative results. In 1883, Hermans of the Hygienic Institute in Amsterdam, concluded that the discomfort of crowded places was due to the inability of the body to cool itself in a hot, moist atmosphere. These symptoms then were due to stagnant, hot, moist air surrounding the body, and would be accentuated in people wearing heavy, impervious clothing that prevented access of moving air to the skin. It was evident then that they should wear as little clothing as was consistent with comfort. The result of these elaborate experiments was in brief that fresh air was good, not because it supplied oxygen, not because it was overloaded by carbon dioxide, not because it contained no poisonous element, but because it allowed the body to exist under such circumstances that it could control its moisture and temperature. They had to combat the traditional fear of drafts and the habit of many people of living in close, hot rooms. The cold air of winter was much more stimulating and produced better results in children than the mild air of spring and autumn. The best results from fresh air were obtained by keeping the children out of doors day and night. Out-of-door sleeping porches enclosed on three sides and roofed, but open to the south, furnished the best fresh air at night, while in the day time balconies and rooms without heat and windows wide open supply the air they needed. They should see that the children were not sealed in heavy, impervious covering so that the skin was unable to rid itself of the heat and the moisture. In all the acute infectious diseases Dr. Freeman believed that there was now a general acceptance of the advantage of fresh air, excepting perhaps, in measles and scarlet fever. In tuberculosis and pneumonia there was no question of its advantage. It would seem that some explanation was due as to why, if all these statements were true, children were still housed and many adults had a panic if a breath of cold air struck the back of their necks or their bald heads, while children who were brought up without fear of cold enjoy it wherever it struck. It was sincerely to be hoped that many of the coming generation might be brought up under different ideas and might be less dependent on hot, offensive, stagnant air for the supposed comforts of life.

Recent Progress in Our Knowledge of the Physiological Action of Atmospheric Conditions.—Dr. FREDERICK S. LEE of New York (by invitation) said that recent experiments in the physiological laboratory of the Columbia School of Medicine had changed their ideas concerning the physiological action of atmospheric conditions. It had long been the custom to ascribe to chemical components of the atmosphere the bad effects of living in air that had already been breathed by human beings. They now knew that, except under very extraordinary circumstances, the harmfulness of respired air was not due to its chemical components. The harmfulness of living in confined air was found in certain physical rather than chemical features—the air was too warm, too moist, and too still; and if it had not these physical features it was not harmful. By way of a general summary it might be stated that when an existing external temperature was fairly comfortable to the individual an elevation of it, especially when such elevation was accompanied by an increase of humidity, was deleterious. This went to demonstrate that a moderately dry and cool air in motion constituted the most physiologically helpful aerial envelope of the body. In these days they heard much of "fresh" air and its merits. They had fresh air funds, fresh air schools, and fresh air babies. All were commendable, but while giving to their funds, opening their schools, and putting their babies out of doors, let them closely understand what constituted fresh air. The freshness of so-called "fresh" air laid, not in more oxygen, less carbon dioxide, less organic matter of respiratory origin, and the hypothetical presence of a hypothetically stimulating ozone, but rather in a low temperature, a low humidity, and motion.

Some Studies on the Mode of Infection in Pyelitis in Infancy.—Dr. RICHARD M. SMITH of Boston presented this paper. He said there had been two antagonistic theories to explain the mode of infection of the kidney in pyelitis of infancy; one maintained that that infection took place through the urethra, bladder and ureters; the other that the infection came by means of the blood and lymphatics. The disease was much more common in the female than in the male, the proportion being nearly 3 to 1. The organism most frequently causing the disease was the colon bacillus. Directly against the ascending theory of infection were the facts that colon bacilli had never been shown to pass up the normal unobstructed ureter and that the colon and tubercle bacilli had been introduced repeatedly into the bladder, and in the presence of a normal mucous membrane and were excreted without causing damage of any kind. Ascending infections occurred only in the presence of obstruction to the outflow of urine and would not occur if the sphincter of the ureter was normal. The theory of infection of the kidney by the blood and lymphatics rested upon much surer ground. Dr. Smith said that he had made seventy-one cultures from the vagina, vulva and urethra of forty infants and young children. One infant six hours old and all over eighteen hours, except one child who was six days old, showed growth from the vaginal culture. All the vulvar and urethral cultures were positive. The first organisms to appear were streptococci and staphylococci, and then the small bacilli, not colon. Colon bacilli were found in vaginal cultures of infants as early as the fifth day. Dr. Smith said that his findings were in accord with those of Semidgall, who found the vagina of new-born sterile ten out of thirteen times and by the second day a profuse growth of cocci. The colon was isolated twelve times out of twenty-one in new-borns after the second day. It was also shown that the vaginal secretions did not kill off the pathogenic organisms. A possible source of infection with colon bacilli or other bacteria was certainly present in the vulva, urethra and vagina, and a slight trauma might easily accomplish the entrance of organisms into the lymphatic vessels and blood, and thus to the kidney. The source of infection in pyelitis, in the majority of instances, males and females together, was the gastrointestinal tract. Some infections might arise from infection in the skin, teeth or tonsils and in some local septic processes.

Diet and Growth in Infantile Scurvy.—Dr. ALFRED F. HESS of New York City read this paper, in which he reported the results of observations on infants fed on pasteurized milk alone. He said there had been considerable difference of opinion as to whether pasteurized milk could induce the scorbutic condition. In its report in 1912 the Commission on Milk Standards stated that pasteurization did not destroy the chemical constituents of milk and that it was not altered by exposure to heat under 145° F. for thirty minutes. In order to test the validity of this statement he had made a test among a certain number of inmates of an infant's

home, where all the babies were fed on Grade A pasteurized milk which had been heated to 145° F. for thirty minutes. The babies had been receiving orange juice in addition. This was discontinued. No other change was made in the diet. Almost all the babies who did not receive orange juice developed a more or less marked form of scurvy, whereas those who continued to receive orange juice remained entirely free from this disorder. The results of this investigation were questioned by some who were loathe to believe that pasteurized milk could in any way lead to scurvy and hence the observations were continued during the following year. The results were the same, so that the writer felt safe in saying that a diet of pasteurized milk led to the production of scurvy in infants unless some antiscorbutic food was also given. The scurvy met with in infants fed on pasteurized milk was as a rule not of the florid type met with in infants fed for months on proprietary food, but might rather be described as latent or rudimentary. There was a gradually increasing pallor, failure to gain in weight, the development of some petechial hemorrhages, and, in the more marked instances subperiosteal hemorrhages. It seemed probable that this type of the disorder was far more common than was generally recognized by physicians and that there were many infants suffering from slight nutritional disturbances which might be attributed to this cause. It was not to be inferred from these conclusions that the use of pasteurized milk was fraught with danger, but merely that it was an incomplete diet for babies and must be given with antiscorbutic food. There were also secondary factors contributing to the development of scurvy, such as the individual variation depending upon hereditary characteristics, that was up on the amount of antiscorbutic material which the infant brought with it when it came into the world. Secondary food factors also seemed to play a part. Malt preparations seemingly predisposed to scurvy, and it seemed that there was an intimate relationship between the development of scurvy and the amount of carbohydrate in the diet. The sovereign cure for scurvy was orange juice, which was efficacious even when boiled for ten minutes. Boiled potato might be used in infant feeding when orange juice could not be readily obtained. One tablespoonful of mashed potato to one pint of water might be used instead of the usual cereal decoction. In connection with this study observations were carried out to ascertain the effect of infantile scurvy on growth. It was found that although the infants continued to gain in most instances for a few weeks following the discontinuance of orange juice, they soon reached a stationary plane and for months were unable to rise above this level, but increased in weight promptly when the antiscorbutic food was again added to their diet. It was also found that scurvy had a direct effect upon the growth in length. Lack of growth, however, did not always play an essential part in the constitution of scurvy. Orange juice was found to be a corrective for the lack of growth as well as for the failure to gain in weight in this series of cases. There was no reason why orange juice might not be given to an infant at the age of one month and there were many arguments in favor of giving it at this early period.

Dr. L. Emmett Holt of New York said that for several years he had held the view that pasteurized milk was responsible for a number of cases of scurvy, and during the past year this view had been confirmed. While they all recognized the advantages of pasteurized milk, it would be a mistake to approve of the commercial pasteurization of all milk. On the other hand, they all knew of instances in which the milk was inadequately certified and physicians did not wish to be responsible for such conditions. As Dr. Hess had pointed out, scurvy was caused by many other things, there were additional factors and hereditary predispositions to be taken into account. There were comparatively few cases caused by pasteurized milk alone. Still, he thought it would be advisable that they should band together to counteract the present tendency to pasteurize all milk. Ten or twelve years ago nearly all the cases of scurvy came from the continued use of proprietary foods while to-day it comes from pasteurized or boiled milk. The point to be emphasized was that if they used pasteurized milk an antiscorbutic must be used early and continuously.

Dr. Samuel S. Adams said he had always been opposed to commercial pasteurized milk, but he did not necessarily object to pasteurization in the home. The reason he was so much opposed to commercial pasteurized milk was because the milk was so often contaminated before it was pasteurized. He said he had seen four cases of scurvy within the last week in the city of Washington which were due to pasteurized milk.

Dr. A. D. Blackader of Montreal said he wished to emphasize the importance of pasteurized milk as a cause of scurvy. He said he had seen two instances in infants brought to him because of obscure symptoms, partly nervous and associated with lack of growth, but with no classical symptoms of scurvy. There was a rapid disappearance of all the symptoms following the addition of orange juice to the diet of these infants. When he saw these cases he thought he had observed something new, but Dr. Hess had anticipated him in describing this subacute type of scurvy due to a deficiency of vitamines.

Dr. Henry L. K. Shaw of Albany, N. Y., said he wished to defend pasteuried milk, as his experience with epidemics of milk borne sore throats led him to believe the danger of raw milk much greater in this direction than the danger of developing scurvy. They had had seventeen epidemics of septic sore throat in New York State directly traceable to milk and in one of these there were seventy cases. There had also been some fatalities. The danger of septic sore throat was, in his opinion, greater than the danger of tuberculosis from raw milk. On the other hand, scurvy was not a fatal disease and could easily be prevented or cured, so that he thought the weight of evidence was in favor of pasteurized milk.

Dr. Percival J. Eaton of Pittsburgh, Pa., said that commercially pasteurized milk was not really a perfectly pasteurized milk. It was pasteurized with overheated steam at a pressure of fifteen pounds and that process produced a sterilized milk. One got better results with a certified milk pasteurized at home.

Dr. Samuel McC. Hamill of Philadelphia said he was not opposed to the pasteurization of milk; in the cities this was necessary. There was, however, a tendency to favor the pasteurization of all milk so that one would be unable to get raw milk. This would be a mistake and it was time to take some action. The medical profession was largely to blame for this attitude of health officers and dairymen. But in any action that this society took in this matter it should state very definitely what pasteurization of milk meant. Dr. Hamill said he believed in the pasteurization of milk, and while it was not always done satisfactorily at the present time it was done better than formerly.

Dr. Henry L. Coit of Newark, N. J., asked Dr. Hess regarding the condition and vitality of the children upon whom he had based his deductions; he said he would like to know something of their heredity and environment. He also thought the tendency to pasteurize all milk was a most disquieting thing to medical men. In instructing mothers as the their home modification of milk he said he had abandoned the use of the word pasteurize. He had found that the word "refine" had a hypnotic effect on the women so he instructed them how to "refine" certified milk.

Dr. Henry Heiman of New York City said we should have laws to govern the commercial pasteurization of milk. One could not always be sure whether a child was getting pasteurized or sterilized milk. Frequently the mother in heating the milk at the time of feeding raised it to too high a temperature. One could give five drops of orange juice, or pineapple juice, to an infant at the age of one month. Simply giving the fruit juice would furnish the missing link.

Dr. Maynard Ladd of Boston said he had seen a half dozen cases of scurvy produced apparently on raw milk and was not able to account for it at first, but found on investigation that the milk was overheated at the time of feeding, so that the children were getting practically pasteurized milk.

Dr. Alfred F. Hess, in closing the discussion, said the conclusion to be drawn from the paper was not that pasteurized milk had not an advantage over raw milk, but only that pasteurized milk was not a complete food for an infant, and that it was necessary in addition to give orange juice, or potato water, or some other antiscorbutic. The commercial potato flour would not do. Dr. Herman asked why the boiling did not destroy the vitamines of the orange juice and did destroy those of the milk? That may be explained by the fact that the change that a substance underwent in boiling was dependent upon the medium in which it was boiled. The vitamines might stand boiling in water but not in fats, such as milk. As to the condition of the children and their environment, the environment

was of the best and the children were normal and had been under observation for a long time, most of them from birth.

Sarcoma of the Kidney Treated by X-Ray.—Dr. ALFRED FRIEDLANDER of Cincinnati said that it was generally accepted as axiomatical that the only hope in cases of sarcoma of the kidney in childhood laid in early nephrectomy, but even with this procedure the mortality was very high on account of the likelihood of metastases, even in those cases in which the operation was well borne. This patient was four years of age and was admitted to the Cincinnati General Hospital on October 20, 1915. The history was one of increasing languor and lassitude, with loss of appetite and anemia. Except for the condition of the abdomen, the physical findings were not of moment. The entire left abdomen was filled by a tumor extending from the costal margin in the nipple line to 3 cm. above the umbilicus. It was hard, distinctly nodular, apparently not tender to touch, and could be moved forward by pressure from behind. Urinalysis on admission showed distinct microscopic hematuria. The blood showed a secondary anemia. Fluoroscopic examination with the colon partly filled with gas showed a sharply defined dark shadow in the region normally occupied by the kidney. *X*-ray plates of the lungs for the characteristic metastatic sarcomatous shadows were negative. The *x*-ray treatments were given because of the apparent hopelessness of the case. After the seventh treatment it was noticed that the tumor had decreased very markedly in size. Later the child had an attack of influenza, then one of measles which was followed by death. The autopsy revealed a sarcoma of the left kidney with small metastases in both lungs and in the liver.

Transient Abdominal Tumor in a Child of Five Years, with Redundant Colon.—Dr. GEORGE N. ACKER and Dr. EDGAR P. COPELAND of Washington, D. C., reported this case. Dr. Copeland said that in December, 1914, a year before his first examination, the child became suddenly ill in the night, with extreme nausea, severe vomiting, and the appearance of a rounded tumor in the hypogastrium, simulating a distended bladder. The tumor was elastic, but not specially tender to the touch. The physician made a diagnosis of intussusception, but a few hours later he was surprised to find that the tumor had entirely disappeared, and the patient made a good recovery. Since this initial attack, others had occurred at varying intervals, seldom less than three weeks, and on several occasions as long as six weeks, apart. The tumor had invariably appeared first over the region of the bladder, moved about the abdomen spontaneously, and finally disappeared. Its appearance was always associated with nausea and vomiting, and its disappearance with a pronounced paroxysm of abdominal pain. When Dr. Copeland first saw the patient he found him in bed on his back with the thighs partially flexed. The attack then was several hours' old, and there was still some nausea. Presenting in the hypogastrium was a smooth, rounded tumor about the size of an orange, elastic but not tender, and dull on percussion. It strongly suggested a distended bladder. There was a well-pronounced beading of the ribs. The pulse was rapid, but regular. The temperature was normal. The leucocyte count was 11,500. The von Pirquet and Wassermann tests were negative. Under restricted feeding and large enemata slowly administered the mass spontaneously disappeared.

The clinical history, in the light of the *x*-ray findings, would seem to justify the assumption that the phantom tumor was the result of a temporary kinking of the redundant colon or sigmoid incident to its displacement to the right, which was followed by either fecal or gaseous distention in the loop. When the loop filled itself to a certain point, it swung gradually to the left and automatically unkinked itself with a disappearance of the tumor mass.

Report of a Case of Influenza in an Infant with Two Unusual Complications—Purpura and Subcutaneous Emphysema.—Dr. HENRY T. MACHELL of Toronto, Canada, reported this case. The baby when seen in consultation was 6½ months old and had always been well and healthy. The child was taken ill with grippe on March 28 and was seen by Dr. More on April 6. There was then a well-developed lobar pneumonia of the right base. The temperature was 104° Fahr., pulse 140, and respirations 60. There were purpuric rashes over parts of the body, the face, particularly the chin, the shoulders, arms, chest, legs, and feet. The petechiæ varied in size from a mere dot to one patch on the left shoulder the size of a ten-cent piece. Another patch on the left cheek was slightly smaller. These large spots had a punched-out feeling to the palpating finger as though they had previously contained fluid. The skin was unbroken. The mother stated that this rash had been present from the first appearance of the illness. On April 13 there was noted a slight swelling at the sides of the neck, under the chin, and down over the upper part of the chest. This swelling continued to increase until two days later, when he was again called to see the child. The swelling around the neck, cheeks, and chest had increased to such an extent that the chin was crowded upward and the head forced backward. It was tense, tympanitic, and crackling under the fingers. It was symmetrical in size and obviously emphysematous. He said that this was the first time he had seen purpura or emphysema as a complication or sequel to influenza either in his own practice or in consultation. The emphysema gradually improved and within five days from the time he had last seen the patient it had almost entirely disappeared. On April 19 the child had an extra severe coughing spell, when the emphysema suddenly became more marked, his breathing became embarrassed, and he died within twenty-four hours. An autopsy was not allowed. Purpura as a complication of influenza was rare. Emphysema had been mentioned as occurring occasionally in pertussis, bronchitis, etc., but he had not seen it mentioned in connection with influenza.

A Brief Report of Sixty Blood Examinations in Infancy with a Review of the Recent Literature of the Blood in Infants.—Dr. M. H. MCCLANAHAN and Dr. A. A. JOHNSON of Omaha presented this report, which Dr. McClanahan read. He stated that while the study had required a great deal of work the results were very briefly stated, that was that his observations were practically in accord with those already published in the literature. He reviewed the literature and compared his findings with those of other investigators.

The Creatin and Creatinin Content of the Blood in Children.—Dr. BORDEN VEEDER and MEREDITH JOHNSON of St. Louis presented this communication, which was read by Dr. Veeder. After citing the results of the estimation of the creatin and creatinin content of the blood by Folin and Denis, Myers and Fine, and Meyers and Lough, he stated that very few such observations had been made on children. In children the non-protein content of the blood did not vary in any marked degree from that of the adult. Tileston and Comfort made determinations on 51 children with a variety of clinical conditions. Normal children gave values of 20 to 34 mg. per 100 c.c. of blood. In normal infants the non-protein nitrogen content had been found to vary between 23 and 44 mg. per 100 c.c. by Schultz and Pettibone. The method used in the study presented were those of Folin and Denis for the non-protein nitrogen and of Folin for the creatin and creatinin. Determinations were made on 70 children. The blood was taken early in the morning before the children had had their breakfast. The cases were grouped into normals, scarlet fever at the time of exanthem when there was an elevation of temperature, afebrile scarlet fever in the first week, and a number of examinations made in the third week of canvalescence when the urinary findings were negative. In addition a number of miscellaneous cases were investigated. The creatinin figure for normal children varied from .58 to 3.44 per 100 c.c. In 10 children the figures were under 2 mg. and in two above. The febrile scarlet fever cases varied between 1.08 and 3.82 mg., but with one-half above 2 mg. and nine under 1 mg. The highest figure in the early febrile case was 3.78. There was no specific retention in any of their cases, although as a whole the figure for the creatinin content of the blood in children was somewhat higher than for adults. A comparison of the creatinin content with the non-protein nitrogen showed that as a general rule both the non-protein nitrogen and creatinin were within the same general limits as had been found for normal adults, and as Tileston found for the non-protein nitrogen in children, although the average figures for both were a little higher in children. In six cases of nephritis which they studied the retention figures were not high and but one case was fatal. This was not a uremic case. The non-protein nitrogen was not increased in two cases and the creatinin was normal in three. In one case with a low protein figure the creatinin was high and in two the opposite condition held. As the nephritis in a given case improved the amount of retention decreased. A number of cases of scarlet fever were followed from

the stage of the acute exanthem until desquamation was completed and tests were made weekly for five weeks. None of these cases developed a typical post-scarlatinal nephritis in the third or fourth week. After the acute febrile period was over there was usually a slight fall in the non-protein nitrogen and creatinin, although in the second week a few showed a slight increase. There was no apparent relationship between the amount of creatin and creatinin. Dr. Veeder said they had found much less creatin in the blood of children than Folin reported having found in adults. Folin found about 10 mg. per 100 c.c. and they had found in children rarely over 5 mg. per 100 c.c. This was interesting in view of the fact that creatin was found in the normal urine of children and was not present in the urine of adults. They had been unable to find any specific relationship between the amount of creatin and creatinin, or any relationship between the amount of creatin and the clinical condition. There was no fixed relation between the total non-protein nitrogen and the creatinin-creatin content. Dr. Veeder also reported observations on a child starved for other purposes and a few experiments as to the effect of copious water drinking and a fixed diet, and also of the effects of a fixed creatin-free diet. The child during the period of starvation showed a slight increase in all three substances during the period of starvation. The results of the experiments in diet and water drinking were negative.

The Hospital Care of Premature Infants.—Dr. L. E. La Fétra of New York presented this paper, which he stated was a résumé of his personal experience in the observation and treatment of these cases. During the past two years they had admitted to the premature ward of Bellevue Hospital 278 premature infants. Of these 13 were still in the ward and 265 had been discharged. The mortality among these infants was very high, but most of it occurred during the first few days after admission to the hospital. The records of the last 200 cases showed that 30 were saved and discharged as cured that was, strong enough so that their mothers could care for them successfully. Of the 170 that died, 90 died on the first day and 118 within the first three days. It was most unusual that a baby weighing less than 2½ pounds was saved. The greatest number of infants admitted to the premature wards had a history of utero-gestation of seven and seven and one-half months. Aside from the small size and weight of these infants they were extremely feeble muscularly, and this feebleness extended to the muscles involved in the acts of sucking and swallowing. In many instances this latter weakness was the underlying cause of fatal inanition. The symptoms manifested by these babies were subnormal temperature, imperfectly developed skin, so that the premature infant radiated more heat proportionately than the normal infant. Again, the heat regulating centers seemed not to be in satisfactory operation, so that the baby was very susceptible to the heat changes of its environment. These babies also show a tendency to cyanosis and are extremely susceptible to all sorts of infection. Absorption from the gastrointestinal tract of deleterious substances, whether as the result of fermentative processes in the intestines or of germ infection might cause profound and even fatal disturbances in a very short time. General sepsis might arise from this source or might come from the umbilical wound, or from an abrasion of the skin. In the general management of these children the aim was to reproduce in as far as possible the conditions of intrauterine life. The baby should be kept in an even temperature approximating that of the body and should be shielded from all sorts of external shocks whether thermal or mechanical. The skin should be protected from all chance of contagion and injury and the eyes should be protected from light. Dr. Le Fétra said he was not in favor of using incubators. The plan of setting apart a small room as an incubator room was far more satisfactory. Here the baby did not undergo any chilling when the clothes were changed. Probably the most satisfactory incubator was that devised by Dr. Edwin B. Cragin and described in the *Journal of the American Medical Association* for September 12, 1914. At Bellevue they were using the sunny corner of a ward facing south, which had a capacity of ten beds and a cubic air space of 1,000 cubic feet per infant. After much experience they had found that babies did best when kept in a temperature of 76° F. to 80° F. with a humidity of 60 to 70 per cent. In their ward the moisture was obtained by keeping a large pan of water simmering on an electric stove. Premature babies should be handled only when necessary to change the gauze diaper. The clothing should be the simplest possible. Babies weighing less than four pounds should be wrapped in cotton until the temperature remained constantly at normal, and the weight had risen to four or four and one-half pounds. In general, the most satisfactory method of feeding these babies was to use the Breck feeder, since this had the advantage of teaching the baby to suck. In some cases the baby could not swallow satisfactorily, and then one had to resort to gavage. The food most suitable and that requiring the least digestive effort was breast milk. The milk was to be expressed from the breast two or three times a day and a requisite amount mixed with whey or barley water or granum as a diluent and then fed to the baby through the Breck feeder. At Bellevnue they used one-half breast milk and one-half whey at first, one ounce being given every one and one-half to two and one-half hours, depending upon the size of the baby and its stomach capacity. If it was impossible to obtain breast milk, the following might be substituted: cow's milk, 6 per cent.; top milk, five ounces; whey, 10 ounces, and five ounces of Imperial granum, to make a 20-ounce mixture. To this was added milk sugar or dextri-maltose, one-half to one and one-half ounces. The number of calories required by the premature baby was much higher than for babies at full term; it was necessary to increase the calories to one and one-quarter to one and one-half times the ordinary requirements. An important apparatus in the premature room was the oxygen tank, which should be kept coupled up and ready for use in case of cyanotic attacks. As to prognosis, weight was the best criterion they had, but one must not despair of even the smallest babies. If a baby survive for a week it had a better chance of living, since the fact of its having survived that long augured a good constitution.

Dr. B. S. Veeder of St. Louis said that in St. Louis they were using a small room in St. Louis for the care of premature infants. The room was heated from a closet, the temperature kept at 80°, or somewhat above, and the children were practically not dressed at all. They were feeding more than 125 calories, usually about 185 calories.

Dr. J. P. Sedgewick said Dr. Le Fétra had spoke of feeding the babies every hour and a half or two hours. It was possible to have the premature babies do well on four-hour feedings. They gave them more than the capacity of the stomach would indicate. The calories usually ran from 120 to 150. They started with 10 or 15 c.c., usually five times daily, or 75 c.c. a day, and increased this amount as rapidly as the infant could take it, but had no regular rule of putting so much into a child at such and such a time.

Dr. B. Raymond Hoobler described an improvised incubator that could be made in a home, by means of a clothes hasket and barrel hoops, covered with klankets and heated with electric light bulbs, black cloth being used to keep the light from the eyes.

Further Experience with Homogenized Olive Oil Mixtures.—Dr. Maynard Ladd of Boston read this paper. He called attention to the fact that in a paper read before the American Pediatric Society, in June, 1915, he had described the homogenizing machine of M. Gaulin of Paris for purposes of modifying milk for difficult feeding cases, especially those showing intolerance for fat. It was possible by this process of homogenization to improve the emulsion of a modification of cow's milk so that it would be even finer than that of breast milk without altering in any way the chemical properties of the milk. There was reason to believe a milk so treated might be better digested and assimilated. Still more interesting was the possibility of substituting some other fat than the fat of cow's milk in cases of malnutrition, in which it was often difficult to make a child gain normally in weight without precipitating sooner or later a digestive crisis. It appeared reasonable in certain cases in which the child responded to breast milk containing two to three times as much fat as cows' milk to question whether there was an intolerance to fat or whether there was something in the cows' milk fat that was not present in breast milk. The principal differences in the fats of cows' milk and human milk were in the size of the fat globules and the proportion of volatile fatty acids. Olive oil was almost wholly olein and palmatin and free from volatile fatty acids, which formed a large proportion of the cows' milk fat. This fact had led him to suggest the use of olive oil in order to obtain the fat percentages in modified milk mixtures and so to eliminate

the volatile fatty acids, and also to secure an emulsion as fine or finer than that of human milk. The milk sugar and protein were to be obtained from skimmed milk as usual; and additional carbohydrates, in the form of dextrin-maltose and starch, were prescribed according to the usual indications. Dr. Maynard said he had applied this method of feeding to 37 cases, including practically all the cases of difficult feeding that he had opportunity to study. In this series of 37 cases, whose average gain on previous feedings was five ounces per month, for a period of 6.3 months, on the homogenized olive oil substituted for the fat of cows' milk the average gain per month was 18.15 ounces. The average period of the homogenized oil feeding was 4.7 months, a sufficient time to determine its permanent effects. The improvement in the babies' general condition had been as striking as that of their gain in weight. Vomiting and sour regurgitation, when present as symptoms, were quickly relieved. The child improved in strength, in the quality of its fat, and in the development of its functions. The appetite improved rapidly and the stools soon became normal in appearance, if the sugars were intelligently prescribed. (By this he referred to proper proportions of dextrin and maltose.) Barley water was used in nearly every case. In some cases the mixture was heated to 212° F.; in others given unheated. Lime water was usually given in amounts of 5 to 10 per cent. of the total mixture, but not as a matter of routine. The percentage of olive oil was almost invariably started at 1.5, and did not exceed 3.50 per cent. The total carbohydrate was usually started at about 5 per cent and never exceeded 7 per cent. The protein was started at 1.50 per cent. and seldom exceeded 2 per cent. In his opinion hunger was the safest guide as to the child's tolerance to the amount of fat it was taking.

Dr. Ladd also described his experience with olive oil mixtures in infectious diarrheas due to indigestion and fermentation. The general scheme of treatment was as follows: After the initial period of catharsis and starvation, a fat free lactic acid milk, diluted two-thirds and one-half, was given. If the infecting organisms proved to be of the Flexner or Shiga type dextrin-maltose was added up to 4 or 5 per cent., and sometimes barley water. If the gas bacillus was present no carbohydrates were added. After a period of several days, when the acute febrile disturbance showed distinct signs of subsiding, olive oil was homogenized with the lactic acid milk in percentages of 1.00, 1.50, and, if well tolerated, 2,00, thus adding considerably to the caloric value of the food. The results briefly summarized were as follows: There were 19 cases of infectious diarrheas on the service of Dr. Wyman at the Floating Hospital, 15 of Flexner bacillus type, one of gas bacillus, and three undetermined. Four cases died, giving a mortality of 22 per cent., about the same as in the other service. Of the 15 cases that lived, eight were in the hospital on an average of 21 days each, and lost over their entrance weight 15 ounces. Seven were in the hospital on an average of 14 days each, and gained an average of 10.7 ounces over their entrance weight. Whether this showing was better or worse than the other services they had no statistics to show. In the writer's opinion, however, based on this limited series of cases, olive oil homogenized could be given safely after the severe acute febrile stage had passed and in the period of convalescence, and was more effective in making up the loss of weight than the fat of cows' milk. A study on fat metabolism of infants fed on homogenized milk was carried out on the Boston Floating Hospital during the season of 1915 by Dr. C. H. Laws of the University of Michigan, the results of which were decidedly significant and justified the belief that homogenized milk mixtures and the substitution of cows' milk fat offered an additional and valuable resource in infant feeding in cases of difficult digestion with malnutrition.

A Method of Preparing Synthetic Milk for Studies of Infant Metabolism.—Dr. HENRY I. BOWDITCH and ALFRED W. BOSWORTH of Boston presented this communication, in which they stated that in connection with their studies concerning infant feeding it became necessary for them to have control of all the factors entering into the composition of the food used, and as only liquid food could be used it soon became evident that a synthetic food from pure materials offered the only solution to the problem. The method by which they obtained this consisted of four steps: (1) The preparation of the isolated food material for use in the synthetic milk. (2) The recombining of these materials to give a mixture of the desired composition. (3) The emulsification or homogenization of the fat and any of the solid or insoluble constituents entering into the composition of the food. (4) Pasteurization or sterilization of the food after it had been made. The substances used were pure water, pure fat, pure sugar, pure protein, pure salts of various kinds, and the protein-free milk of Osborne and Mendel. In some cases they had used sugars of the purest commercial grade, while in others they had used recrystallized lactose. The purest commercial olive oil was used and butter fat prepared according to the method of Osborne and Mendel. Thus far they had used only one protein—casein—and had made use of this substance in three forms, calcium caseinate and sodium caseinate of commerce, and pure casein prepared according to their method already published. Osborne and Mendel had shown that a pure synthetic food of pure materials contained no vitamines. But these substances were present in a preparation made by them and called protein-free milk. When the continued use of a synthetized milk was required for more than a few days it was always wise to add some of this protein-free milk in order to get the benefit of the vitamines carried in it. All these synthetic milks had been made up on the percentage basis. The sugar was dissolved in one-half the volume of distilled water required for the complete mixture and the salts added to this sugar solution. The protein was dissolved or suspended in the other half of the water. If larosen or nutrose were used they were rubbed to a fine paste with a small portion of the water, the remainder of the water added, and then the whole warmed to effect complete solution. If pure casein or paracasein was used they might be suspended in the water and homogenized with the fat or they might be dissolved by the addition of alkali, one-half of a cubic centimeter or normal alkali or its equivalent being used to each gram of protein. The two and one-half volumes were now united, the fat melted and added and the whole homogenized. For this purpose the Manton-Gaulin homogenizing machine was used, which was of special design, built for laboratory use. The writer described the machine and the method of cleansing it before use and of passing the mixture through under successively higher pressures until it was thoroughly homogenized, when it presented the appearance of milk. It was then transferred to glass fruit jars and sterilized, lightening jars with glass tops being the best for this purpose. If the food was to be kept for any number of days it should be reheated and then stored in a cold place.

(To be continued.)

Notes on Ureteritis.—Harry Kraus refers to the relatively small literature of this not uncommon condition. This is due to its great infrequency as an isolated affection. In pregnancy the natural results of compression are circulatory disturbance and edema. Here we sometimes see secondary infection of an ascending, probably lymphatic origin. As a rule, however, ureteritis appears to be descending in type and due to disease of the renal parenchyma or kidney pelvis. Clinically the descending form manifests itself at the lower segment. Only in tuberculosis is the entire canal involved. Ureteritis from a foreign body is a local phenomenon, which, by causing dilation or sacculation, may be recognized by the *x*-ray after injection of a contrast fluid.—*The Urologic and Cutaneous Review.*

Thymol from Horsemint.—The recently issued Bulletin 372 of the United States Department of Agriculture deals with this subject. Thymol has been an import, and since the present war the supply has been reduced to almost a tenth of the normal. It is obtainable from our native wild horsemint, and the government experts have learned that under cultivation an acre of improved mint will yield twenty pounds of oil from first plantings, which amount then increases to an annual yield of thirty pounds with a utilizable content of 70 per cent. As thymol is worth at present about $2 per pound, an acre of horsemint will not yield above $40 per annum gross. The cost of production, which includes rents, taxes, fertilizer, growing, harvesting, use of distilling plant, etc., will make the cost of production somewhere about one-half this amount. While this implies a profit of 100 per cent, the margin is not great enough for a safe investment in an untried industry. Other oil-bearing plants could be grown with the mint, with but little increase in expense, and this seems to be the recommendation of the government.—*Southern Practitioner.*

Miscellany.

Luminous Insects and Enzyme Action.—The dependence of photogenesis in fireflies, phosphorescent animals, fungi, bacteria, etc., upon enzyme action has been shown abundantly in the past few years. In 1913 Dubois showed that the mechanism of light production in beetles is bound up in the action of an oxidizing zymase upon an organic protein product in the presence of water. He terms this protein luciferin. It is contained in the form of granules in the photogenic organ while the oxidizing zymase, which he terms luciferose, is dissolved in the blood. When the latter passes the luminous organs the action of luciferose on luciferin gives rise to light. This reaction can be obtained in vitro, using instead of the zymase a chemical oxidizing agent. The luminosity of meat, dead wood, deal leaves, etc., is due to peculiar bacteria, and oxidation is likewise involved here. A hypothetical substance, photogen, is believed to be actuated by light waves in the presence of oxygen. The above jottings are found in an article by Dr. Walter G. Smith in the *Dublin Medical Journal*, June 1, 1916.

History of Diphtheria in Australia.—The records in Victoria began in 1871. From 1871 to 1892 the death rate per million inhabitants varied from 275 to 922, the average being about 521. In 1893 it was but 155 and in 1894, 190. These low figures antedated the use of antitoxin. From 1895 there was a drop until in 1906 the low mark of 47 was reached. The drop was not steady, however, for in 1897 and 1898 it shot up to 270 and 209 respectively. Since 1906 the rate has risen; in 1911 and 1912 it was 181 and 185 respectively. In 1914 it was down to 148. Two factors must play a rôle in these irregularities. First, a recurring exhaustion of epidemic influences; second, the thoroughness or reverse with which the health office is administered. In New South Wales the available records began in 1875. From that period to 1895, when antitoxin was first used the annual death rate per million inhabitants varied from 277 to 768. In 1894 the figure was 378. From 1895 to 1900 it fell steadily to 65. This is the lowest mark reached. Since 1901 the rate has shown great variation. The highest mark was 178 in 1913. In 1902 it was 131. In 1903-1906 inclusive it remained below 100. From 1909 to date (save in 1913) it ranged from 117 to 139. Membranous croup is counted throughout as diphtheria.—*The Medical Journal of Australia.*

"Germano-Medical Sacerdotalism.—W. C. Hossack, Port Health Officer, Calcutta, confesses that he is not a bacteriologist, but thinks the bystander can see some things not realized by the man on the inside. Given sufficient identification marks immutability of bacteria may seem to be proven. Yet some sudden cosmic change like the arrival of the monsoon will upset all the specific characteristics. Thus an "inulin nonfermenter" suddenly becomes an "inulin fermenter." There is a similar liability in regard to anaphylaxis, phagocytosis, immunity reactions, hemolysis, agglutination, etc. The Noguchi test seems to have invalidated the Wassermann test, for the latter is positive for several diseases, and in over a third of the cases of the latter there seems room for a difference of opinion. In other words, it is about 82 per cent. only efficient. What the author deplores is the ceaseless piling up of mere varieties by bacteriologists, which has made their study a dreary chaos, that is leading nowhere. He blames the Germans for this state of affairs because the real progress in bacteriology must be credited to Germans like Koch and Ehrlich and therefore one must not attack the high priests of that science. The only way out is to let other men than bacteriologists pass judgment on what is really valid and stable. If there is mutation its limits must be fixed by something less elusive than percentage fermentations. More stress should be laid on the actual germ recoverable from an infectious case. Chemists, physicists, and other scientists should pass on all matters which involve their respective subjects.—*Indian Medical Gazette.*

THE CLINICAL POSSIBILITIES OF THE PHARYNGEAL PITUITARY.

AN ACCOUNT OF THE CLINICAL RELATION OF THE NASOPHARYNX TO THE HYPOPHYSIS-SYSTEM.

BY W. SOHIER BRYANT, A.M., M.D.,

NEW YORK.

THE intention of this paper is to show (1) that the hypophysis-system may be affected clinically through that portion of the system lying in the nasopharynx, the pharyngeal pituitary, and (2) that the results of clinical treatments of the pharyngeal pituitary are similar to those obtained, in like conditions, by hypophysis-medication.

To illustrate these points I will discuss (1) adenotomy in its relation to the pharyngeal pituiary and the hypophysis-system, and (2) certain postnasal treatments which influence the hypophysis-system by way of the pharyngeal pituitary.

The Pharyngeal Pituitary.—To make this discussion clearer it may be well to include a brief outline of our knowledge of this organ:

The pharyngeal pituitary is a part of the hypophysis-system. It represents the lowermost extremity of Rathke's pouch, the hypophsial pedicle of the embryo, which, failing to emigrate through the cranium, has not disappeared through retrogression, but has become organized, in man, into a true glandular body in the pharynx. The phylogenetic history of the hypophysis-system shows that in the lowest vertebrates, the glandular lobe—itself a portion of the primitive pharynx—is in open communication with the pharynx; this communication is usually lost in the ascending scale, by the chondrification of the base of the skull, but remnants of hypophysisis-tissue remain along the route traveled by the embryonic hypophysis from the ectoderm ic Anlage to the brain. In mammals several hypophysis-remnants or accessory hypophses, have been found in rabbits and cats (Arai) and in dogs. In man the accessory hypophysial tissue takes the form of the hypophysis of the pharynx. Consequently, in contrast to the cerebral hypophysis which lies inaccessible in the sella turcica, protected by the sphenoid bone, this accessory hypophysis-tissue lies exposed at the pharyngeal angle,[1] the most unprotected spot in the pharynx. It is located underlying Luschka's tonsil, and it may be found anywhere within the extreme boundaries—the mucous membrane in the middle line, the posterior margin of the vomer, and the base of the sphenoid.

The pharyngeal hypophysis is known to be present in the fetus and in individuals of all ages up to seventy-six years. In a fetus of 18 mm. it measured 1½ mm. in length (Erdheim); in the adult, its average length appears to be about 5 mm. The shortest length given in the literature is 1½ mm. (fetus); the longest, 7 mm.; the least width, ¼ mm.; the greatest, 3 mm.; the least thickness, 1/5 mm.; the greatest, 1½ mm. These measurements are given here regardless of age. The size of the pharyngeal pituitary has been urged against the possibility of its functional importance. When, however, we consider the average dimensions of the cerebral pituitary (15 mm. in the transverse direction, 8 mm. in the anteroposterior, and 6 mm. in the vertical), in relation to its vital importance in the general economy, it is seen that the size of the accessory pituitary can be no argument against its activity.

According to Citelli, numerous capillaries and small veins are found both within and around the pharyngeal hypophsis; these vessels anastomose with the veins of the pharyngeal mucosa and the submucous tissue as well as with the veins of the periosteum of the lower sphenoid surface and the bone.

Histologically, the pharyngeal pituitary resembles the glandular portion of the cerebral pituitary, but it probably remains more embryonic in structure. The literature emphasizes its histologic variability. My own sections showed strong chromophile elements, with a general structure closely resembling the adrenal.

The function of the pharyngeal pituitary is probably auxiliary to that of the cerebral pituitary. Citelli has found indirect circulatory connections between the pharyngeal hypophysis and the cerebral hypophysis, through a venous plexus in the sphenoid body. There is also probably some nervous connection between them, and it is possible that there may be mutual secretory and stimulative activity between them. In cases of atrophy of the cerebral hypophysis, the pharyngeal hypophysis, very significantly, is sometimes found to be in a state of hypersecretion. The fact that the pharyngeal pituitary is regularly present in man, although very inconstant and often absent in animals, leads Pende to suggest that this gland may possess a high functional importance, perhaps a function of its own, which is different from that of the greater portion of the glandular lobe of the cerebral pituitary. My own theory of the physiological significance of the pharyngeal pituitary is partly explained by its location, which brings it into physiological, as well as anatomical, relations with the lymphoid tissue of Waldeyer's ring. It lies in the median line in close association with Luschka's tonsil, a portion of the defense mechanism of the ring. The pharyngeal pituitary is the representative of the cerebral pituitary located, like the lymphoid tissue, in the most vulnerable part of the body, because the exposure of this portion needed the strongest defense mechanism the body is capable of, which is the pituitary-system.

The Relation of Adenotomy to the Pharyngeal and the Cerebral Hypophyses.—The importance of the pharyngeal pituitary lies in the fact that this external portion of the glandular hypophysis may have its functional mechanism interfered with by the in-

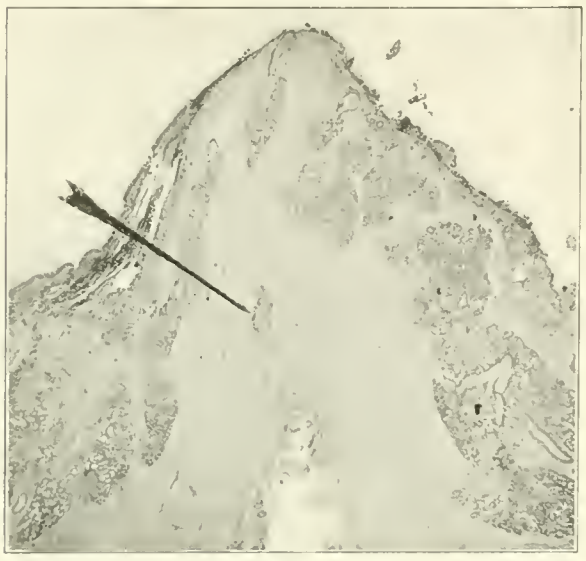

Fig. 1.—This and the following figures show sections of the pharyngeal pituitary of an individual 40 years of age; general paresis; death from bronchial pneumonia. Stained with hematoxylin-eosin. Figure 1 is a section of the anterior portion of the pharyngeal pituitary, showing it situated in midst of the mucoperiosteum, near the superior end of the choanal septum. A group of poorly staining, or clear cells, is seen.

fections of the upper air tract, especially of the rhinopharynx and the pharyngeal angle. Citelli[2] believes that the pharyngeal hypophysis is in functional contact not only with its surroundings, the pharyngeal mucosa and the adenoid vegetations, but also with the cerebral hypophysis. Accordingly, the common inflammations of the pharyngeal mucosa exert an injurious effect upon the functional and the anatomical development of the pharyngeal hypophysis and indirectly upon the cerebral hypophysis. In chronic hypertrophy of the pharyngeal tonsil ("adenoids"), the pharyngeal hypophysis is likewise hypertrophied, as would be most natural considering its relations with the pharyngeal tonsil as component parts of the defense mechanism. Furthermore, if the pharyngeal hypophysis is affected, the cerebral hypophysis is also involved; the bearers of "adenoids" have been known to present a hyperplastic condition of the cerebral pituitary with hypersecretion. Other chronic affections of the nasopharynx which must of necessity involve the pharyngeal pituitary result in pathological changes of the cerebral pituitary. Citelli's[3] findings justify the assumption that part of the associated disturbances with adenoid vegetations represent toxic phenomena in consequence of impaired hypophysial function.

Consequently, it is of great importance that in adenotomy at least one means is afforded of relieving the hypophysis-system of infections incident to its location, and of stimulating it to normal functioning. The clinical relation of adenotomy to the hypophysis-system is revealed in cases of "adenoids"; adenotomy, an operation which impinges upon the periphery of the hypophysis-system, relieves the pharyngeal pituitary, together with the lymphoid tissue, as is shown by the reaction of the hypophysis-system in form of more rapid growth and improved nutrition after this operation. It seems hardly necessary to state that the pituitary-system is known to be of essential importance for the normal course of the processes of growth (see Cushing.[4]) Furthermore, adenotomy relieves a psychic symptom-complex pathognomonic for hypophysial lesions, which is associated with "adenoids" and affections of the nasal passages; this complex comprises loss of memory, partial or complete; aprosexia, mental and emotional sluggishness, and morbid drowsiness and somnolence. The frequent remarkable psychic change after adenotomy is a matter of common knowledge. It is interesting that Citelli[3] states that this symptom-complex can be removed through operative or local treatment of the primary disease, alone; or it can also be removed through general hypophysial treatment without local measures; a certain and permanent recovery is ensured through the combination of these two methods of treatment.

Postnasal Treatments and the Hypophysis-system.—The statements recorded above are all discussed at greater or lesser length in the literature. The writer has now an entirely new statement to make regarding the clinical significance of the pharyngeal pituitary, and will attempt to place a large variety of postnasal treatments on the same level with adenotomy in regard to the hypophysis-system.

The treatment of the post-rhinopharynx is well known and widely used, and its effects are recognized as very important in all infections of this region and their complications. There is great variety of technique used in treating this region; many eminent physicians treat it in routine manner and have done so for a long time. I have a special treatment of the postnasal region, the technique and impirical indications of which were suggested by Dr. E. D. Spear; the treatment consists of an application of irritating fluids—usually ammonia ferric sulphate or hydrogen peroxide—by means of a cotton carrier through the nose, to the vault of the pharynx in the median line from the base of the vomer backwards. For nearly thirty years I have

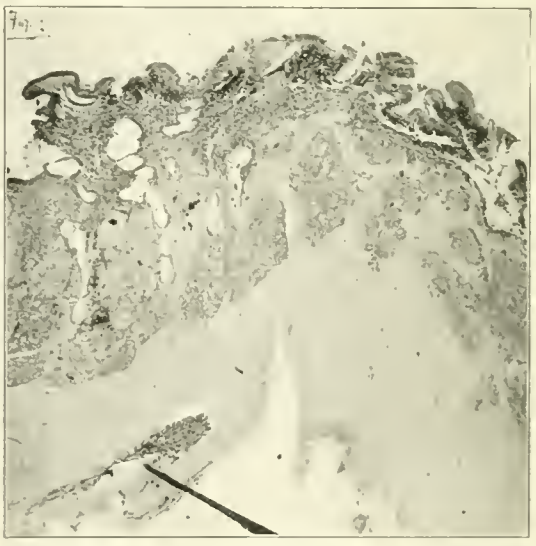

Fig. 2.—Oblique section of the posterior portion of the pharyngeal pituitary, showing its position in the mucoperiosteum of the vomer close to the sphenoid; it is overlaid by the anterior portion of Luschka's tonsil and a great quantity of mucous glands. Chromophile or deeply staining cells appear in the pharyngeal pituitary.

been using this stimulation empirically in (1) hypertrophic conditions of the lymphoid tissue and the mucous membrane of the rhinopharynx with hypertrophic ear conditions, instead of adenotomy; (2) in conditions of the mucous membrane where hyper-

trophy and atrophy in various combinations are associated with atrophic middle-ear catarrh; (3) in atrophic conditions of the rhinopharynx associated with hypotrophic conditions of the middle ear; (4) in otosclerosis; (5) in tonsillitis; (6) in cases of articular synovitis.

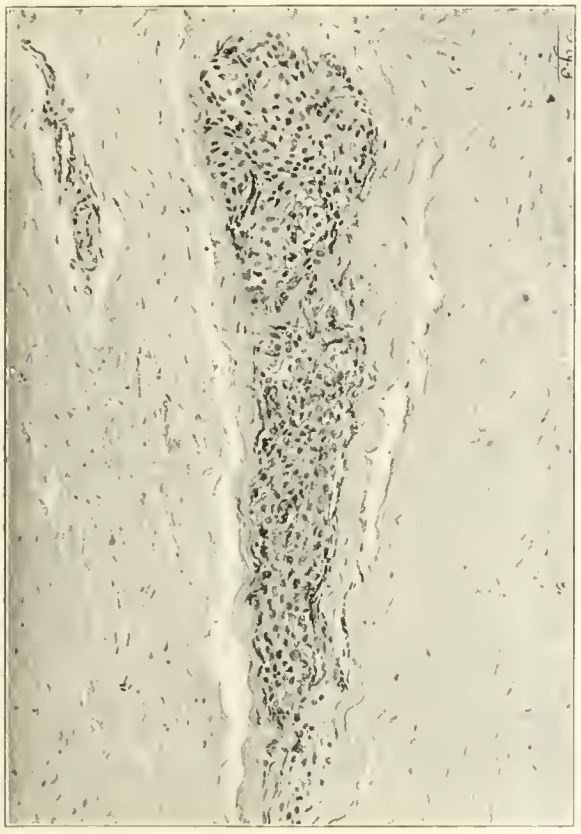

Fig. 3.—Section of the anterior portion of the pharyngeal pituitary more highly magnified. Composed chiefly of clear cells.

The effects of these applications are immediate: after one application there occurs (1) an equalization of the circulation, shown by improved color of the face; a red face loses color and a pale one becomes rosy; (2) the blood tension is likewise equalized; when abnormally low, an increase of tension occurs, whereas, when abnormally high, a reduction generally follows; similarly (3) the pulse is brought from either extreme closer to the normal. Repeated applications are followed by a consciousness of euphoria—an objective general physical improvement. A tonic effect is characteristic. The most striking of these general effects is the regulation of the blood pressure, so that it tends always to approach the normal.

The local effect, in catarrhal ear troubles and in otosclerosis, is an improvement of the hearing; in articular synovitis there is an immediate noticeable relief of pain; fluid in the joints is got rid of, and motion is restored. In the case referred to in my article, "Acute Articular Synovitis of Cryptic Nasopharyngeal Origin,"[5] pain was relieved after the first postnasal application, motion was gradually restored and fluid disappeared completely in eleven treatments.

I had made use of these empirical stimulations for a good many years before I had any understanding of their relation to the pituitary-system. The beginning of my enlightenment as to the real cause of the remarkable results from this form of treatment came when an unknown glandular body appeared (in some sections that I had made of the nasopharynx), which I located as being precisely in the region I had stimulated. This glandular body was the pharyngeal pituitary ("discovered" by Erdheim in 1904). Subsequent investigation revealed it as an integral part of the hypophysis-system, so placed as to be clinically accessible.

After making this discovery of the suggestive location of the pharyngeal pituitary in regard to postnasal stimulations, I compared what is known of adenotomy and its effects on the hypophysis-system with the fact that the results of postnasal stimulations are those associated with the activities of the hypophysis-system; that is, blood tension, pulse rate, and circulation are affected almost immediately and infection is reduced. I then compared the results of stimulating the pharyngeal pituitary with the results of hypophysis-medication in like pathological conditions, and found that clinical treatment of the pharyngeal pituitary by means of chemical stimulation and the introduction of hypophysis-substance into the system are remarkably similar in their results in arthritis, otosclerosis, osteomalacia, etc. Compare, for instance, both the general and the local effects of the chemical stimulation of the pharyngeal pituitary as given above, with those obtained by Whitbeck: "Rheumatic Arthritis Treated by the Extract of Pituitary Body."[6] In his series of cases the regulation of the blood pressure, from high to normal and from low to normal, is strikingly similar to that obtained by chemical stimulations of the pharyngeal pituitary; likewise, the results in the regulation of pulse and circulation are similar,

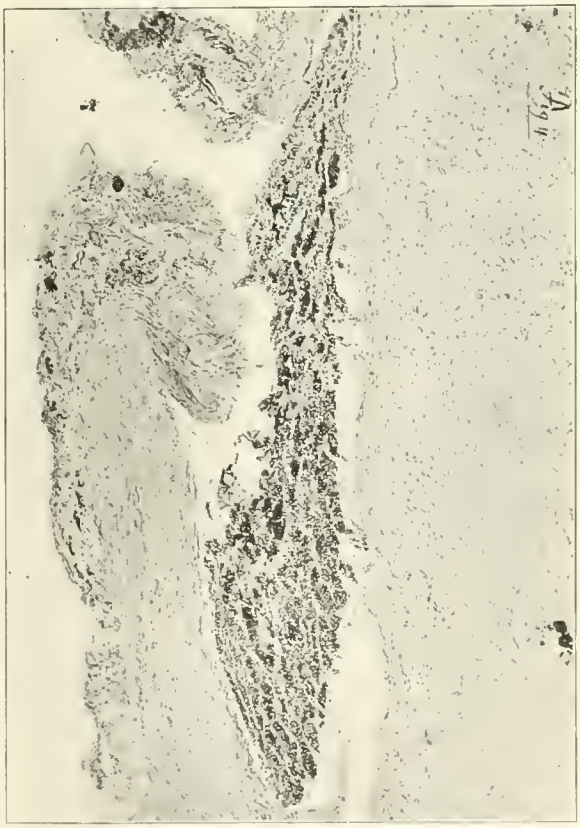

Fig. 4.—Section of the anterior portion of the pharyngeal pituitary showing a structure resembling that of the suprarenal gland.

as are also the local results of relief from pain and alleviation of joint symptoms. Compare also Macy,[7] in whose three cases of gonorrheal arthritis, all inflammation had disappeared and motion had returned after ten days' use of pituitary medication.

Borchardt[8] advises the use of hypophysis-extracts in infectious diseases with a lowered blood pressure and in rachitis. Denker[9] and Citelli[10] connect otosclerosis with hypophysis dysfunction, and Denker looks for good results from hypophysis-medication. Koch[11] has treated osteomalacia successfully by hypophysis-medication; severe pains which were not relieved by narcotics or by antirheumatic remedies were immediately relieved even by a few cubic centimeters of hypophysis-extract, with an especial improvement of the subjective conditions. Likewise, Klotz,[12] Elfer,[13] and Weiss[14] have used pituitary-medication successfully in rachitis or osteomalacia, and there is mention in the literature of its successful use in Still's disease. It is also not without interest in regard to the regulation of the pulse noted above, that Hewlett[15] makes the statement that pituitary extract is the only drug which will convert the abnormal pulse form so frequently seen in fever into a relatively normal pulse form.

As an example (under somewhat different technique) of the effects of stimulation of the pharyngeal pituitary in toxic conditions, the following is striking and illustrative. At the request of another physician I examined the throat and nose of a patient of his, a young woman of twenty-four, who had never menstruated, and who was subject to occasional "crying spells," but who was otherwise apparently normal. When I saw her she had been prostrated for some time, had a temperature running to 101⅘°, and showed a slight swelling and irritation of the adenoid. All signs were negative. As tonsil and nasal treatment did not relieve the lymphoid hypertrophy, I used forcible application in the "adenoid region" of iodine and glycerine, which caused bleeding and considerable discomfort, soon followed by a rise of temperature to a steady temperature of 104°. The case was then diagnosed as typhoid fever, which ran its course and proceeded to convalescence. In this case there was probably a slight chronic hypopituitarism associated with ovarian dysfunction; there was, nevertheless, a sufficiently active pituitary function to respond in form of temperature to stimulation of the pituitary-system. The explanation is that the pituitary-system had been so depressed with toxins that it was too sluggish to react until stimulated.

Conclusions.—It seems possible to say, on the foregoing evidence, that intervention in the region of the nasopharynx whether it takes the form of (1) adenotomy (or of scraping, slitting, finger-manipulation or forcible application to the adenoid), or (2) of chemical application through the nose to the region of the pharyngeal tonsil, affects the hypophysis-system through the pharyngeal pituitary. After adenotomy and chemical stimulation of the pharyngeal tonsil, the results in (1) rapid growth and improved nutrition, (2) in relief from aprosexia and morbid somnolence, etc., (3) in freeing the system of infection and local relief of pain, (4) in the regulation of blood pressure, of pulse, of circulation, and of temperature, all speak for themselves as to the involvement of the cerebral pituitary in the renewed activity of the pharyngeal pituitary. Consequently, it is possible in depressed states of the pituitary-system to supply pituitary activity in either of two ways—the first, by clinical treatment of the pharyngeal pituitary through intervention in the nasopharynx; the second, by supplying pituitary substance to the system. It is very likely possible to combine advantageously the clinical and the therapeutic modes of treatment.

If adenotomy and postnasal treatments are in effect, as we assume, stimulations of the pharyngeal pituitary, by which the pituitary-system is influenced, then, on account of the interrelation of the pituitary, the thyroid, the adrenals, etc., adenotomy and postnasal treatments must influence in some degree the entire glandular system, a fact which in itself is another explanation of the relief after postnasal intervention.

It goes without saying that while for many years physicians have unwittingly been activating the pharyngeal pituitary and the hypophysis-system by treatment of the nasopharynx, any idea that there might be clinical possibilities offered by the location of an outlying portion of the hypophysis-system in the pharynx, has barely been considered. It is of extreme importance to the oto-laryngologist that this gland be investigated and some definite idea of its clinical possibilities be gained. Doubtless, in certain cases, the stimulation of the hypophysis-system through the pharyngeal pituitary might be impossible, as the literature states that it is sometimes atrophied, or composed of Malphigian cells or of pavement epithelia; on the other hand, in certain abnormal cases where an open craniopharyngeal canal persists, which, according to Citelli, are less rare than was formerly thought, postnasal intervention would be quite literally a stimulation of the hypophysis *in situ*. In the great majority of cases, however, as the writer's experience has shown, it is possible to assume a normal pharyngeal pituitary, with functionating elements, which respond to clinical treatment. That this outpost of the pituitary-system lying in the pharynx is of clinical importance in the treatment of certain diseases, is without doubt. And, of necessity, to the oto-laryngologist must belong the responsibility of opening up this new field of clinical work.

Congenital Obliteration of the Bile Ducts.—T. B. Holmes thinks that atresia of the bile ducts is not so extremely rare as is commonly believed; hence every medical man should bear in mind the possibility of its occurrence. It appears to be, in the majority of cases, a developmental anomaly, and in 16 per cent of cases thus far reported the anatomical relations suggested the possibility of surgical relief—an artificial passage to the duodenum, or this absent, a temporary fistula. The actual number of cases of operative cure or relief in comparison with the total number of cases recorded seems to be about 3 or 4 per cent.—*American Journal of Diseases of Children.*

HEREDOSYPHILITIC DENTAL STIGMATA.

By JOHN BETHUNE STEIN, M.D.,
NEW YORK.
PROFESSOR OF PHYSIOLOGY AND DISEASES OF THE MOUTH, NEW YORK COLLEGE OF DENTISTRY.

It has long been known that stigmatism of the teeth may be caused by heredosyphilis.

Syphilitic hypoplasia (misnamed erosion and atrophy) of the teeth, is apparently caused not directly by the *Treponema pallidum* in the tissues of the embryo, fetus, or young child but indirectly by the severe disturbance in the metabolism of the young organism brought about by the syphilitic infection; the extent of the hypoplasia depending upon the seriousness of the disturbance which in turn is determined by the amount and duration of the infection. The syphilitic infection may be so great and the disturbance in metabolism so severe that the cells of the embryo, fetus, or young child are unable to resist it and instead of stigmata being produced, death results.

Syphilitic hypoplasia of the teeth is a subject of great diagnostic and economic importance, but of late has seemed to slumber in "no man's land," interesting apparently neither dentist nor physician.

It is to be remembered that heredosyphilis is essentially the same as self-acquired syphilis, it is syphilis acquired in utero from the syphilitic mother. Syphilis "ab ovo" has not been discovered although the *Treponema pallidum* has been found in the ovocyte.

The study of syphilitic hypoplasia of the teeth presupposes some knowledge not only of the development of the teeth (especially the time when the formation of dentine begins and the height which the so-called dentine cap should normally reach at various periods of the teeth's development), but also of the time of their eruption.

It is also to be remembered that a tooth is formed partly of epithelium (ectodermic in origin)—the *enamel;* and partly of connective tissue (mesodermic in origin)—the *pulp, dentine,* and *cementum.*

The first traces of the teeth (Fig. 1*) are seen in the second month of embryonic life when a groove—*the dentinal or enamel groove* develops along the inner edge of the embryonic jaw. From the floor of this grove an epithelial lamina or ridge—*dentinal ridge, enamel ledge, dental shelf* (Zahnleiste) forms, constituting the anlage of the enamel organs.

The dentinal ridge or enamel ledge develops solid protuberances—*dentinal bulbs or enamel germs* at points where the temporary (deciduous or milk) teeth will later appear; each point corresponding to a temporary tooth. The dentinal bulbs or enamel germs are somewhat knoblike; later, their bases spread and flatten until finally the underlying connective tissue—*dentinal papillæ* projecting up into them make them cup-shaped, each enamel germ grows deeper into the underlying connective tissue, but remains connected by a thick epithelial cord (neck) with the dentinal ridge on the inner (lingual) side of the enamel germs.

The enamel germs become the *enamel organs,* which remain connected by thin epithelial cords (so-called necks) with the dentinal ridge and have the double function of determining the shape of the crowns of the several teeth, and producing the enamel for them.

*I am indebted to Dr. Francis Ováry for the drawings in Figs. 1 to 6. Figs. 2-3 were drawn from sections made in the Histology Laboratory of the New York College of Dentistry.

An Enamel Organ consists of the following layers of cells, viz., (1) An *inner layer of hexagonal cylindrical cells—enamel cells, also called ameloblasts, adamantoblasts,* (2) A *stratum intermedium,* of more or less round cells, (3) A *stellate reticulum,* or an *enamel pulp,* of stellate cells, (4) An *outer layer* of flat cells. See Figures 1-2-3.

The dentinal papillæ growing vertically soon become surrounded on all sides by the cap-like enamel organs, and at the periphery of the papillæ there develops a layer of columnar cells (odontoblasts) of mesodermic origin which form the dentin, by a process thought to be analogous to that observed in the formation of bone, by the osteoblasts. After the formation of a considerable amount of dentine by the odontoblasts, the enamel cells grow in length, and finally from or by them (by the process of amelification) the enamel prisms are formed.

While these processes are taking place a connective tissue covering—*Dental Sac,* which is rich in cellular and fibrous elements forms around each developing tooth. The cementum is thought to be produced from the cells in this dental sac.

The dentine always begins to form at the summits of dentinal papillæ so that dentine caps (Figs 2 and 3) are formed before amelification takes place; later on, however, dentinification and amelification proceed synchronously. The process of dentinification which is remarkably regular proceeds from the summit of the dentinal papillæ and gradually forms the crown, neck and the root of the tooth.

Dentinification takes place much earlier than is generally supposed. According to Magitot and Legros the dentine caps of the teeth begin to form approximately as follows:—

Deciduous teeth: Incisors and cuspids, 17th week of intrauterine life; 1st and 2nd molars, 18th week of intrauterine life. Permanent teeth: 1st or 6-year molars, 6th month of intrauterine life; incisors, 1st month after birth; canines or cuspids, 3d and 4th month after birth; biscuspids, 6th month after birth; 2d or 12th year molars, 3rd year after birth; 3d molars or wisdom teeth, 12th year after birth.

At birth no permanent teeth have begun to calcify except the first molars.

Figure 4 shows the time of the inception of calcification (dentinification) of the teeth.

If the morbid influence of syphilis does not affect the tooth during its development, it erupts complete in form and structure. Syphilitic stigmata upon the teeth can be produced only during the development of the teeth and are the result of some interruption in the process of calcification. Suspended or improperly performed calcification produces irreparable stigmata, which may be seen on any part of the tooth from its morsal surface to its gingival margin depending upon the time when the syphilitic infection is sufficient to produce them. If the disturbance caused by the syphilitic infection is sufficiently active at the time when dentinification is about to begin the hypoplasia will be upon the morsal surface of the tooth, but if the syphilis is active later on, the stigma may show itself at a higher level upon the facial, lingual and mesial surfaces of the tooth, upon that part of the tooth which is then undergoing development. Thus it is possible to tell from the stigmata on the teeth the time when some vicious disturbing influence attacked the embryo, fetus, or new-born child.

The apparent relationship already referred to between the degree of syphilitic infection and the degree of syphilitic hypoplasia of the teeth is indicated by the fact that the hypoplasia of the dentine, and the enamel, may be slight, or extending through various degrees, very marked. The dentine may be covered with but poorly differentiated enamel or

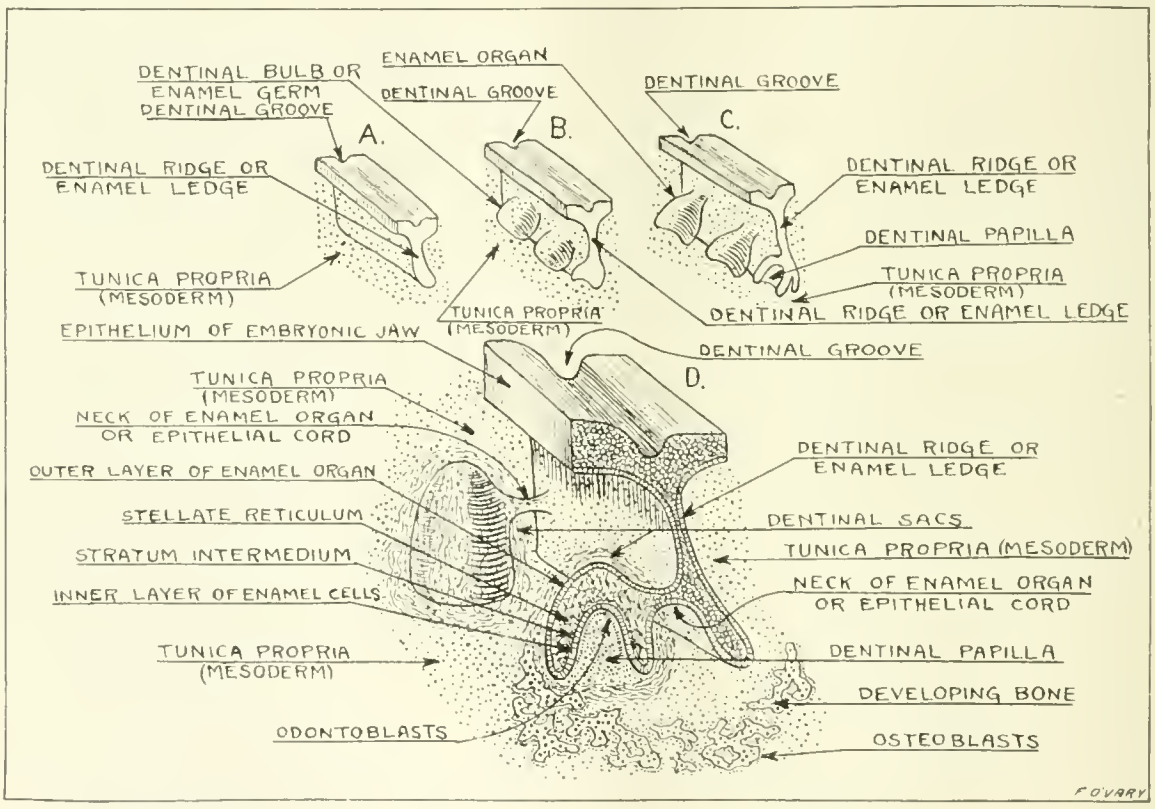

FIG. 1.—Diagram illustrating the earlier periods in the development of the tooth.

no enamel; or the tooth may not be formed at all, the cells of the tooth germ having been destroyed.

Syphilitic hypoplasia of the deciduous teeth rarely occurs, because the beginning of dentinification for these teeth takes place, as we have said, from

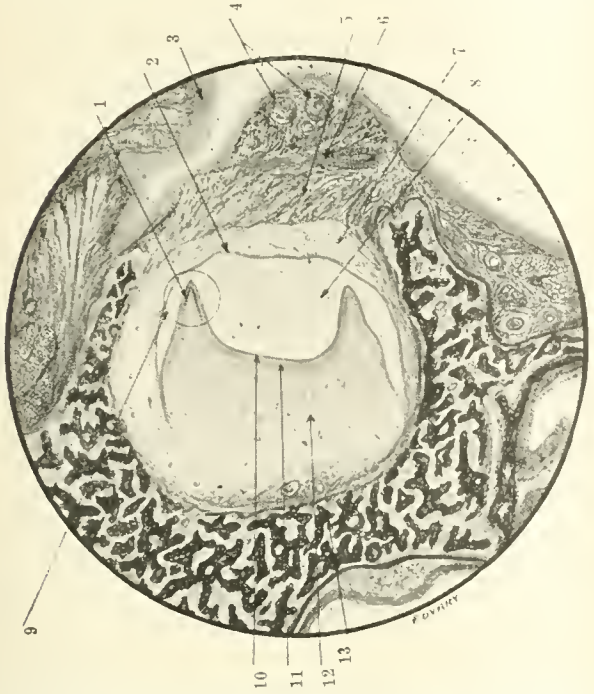

Fig. 2.—A longitudinal section of the left upper deciduous first molar from a human fetus of about four and a half months, showing the early formation of the dentin cap. (Leitz, oc. III, obj. 1.) 1. Dentin cap; 2. outer layer of enamel organ; 3. epithelium; 4. epithelial debris; 5. tunica propria; 6. dentinal ridge; 7. dental sac; 8. stellate reticulum.

about the seventeenth to the eighteenth week of intrauterine life, and if the fetus is infected with syphilis at this time it usually dies. Syphilis is a potent abortionist; but it is possible when the syphilitic mother is given antisyphilitic treatment that the life of the fetus may be saved.

The first molar, incisor, and cuspid teeth of the second dentition are the ones which show frequently the evidences of heredosyphilis, (Figs. 5-6) because the first molars are beginning to undergo dentinification during the last months of fetal life and the incisors and cuspids during the first three or four months after birth. (Fig. 4) It is at this time that the syphilitic process is most intense, frequently causing the death of the fetus or child.

Suppose the syphilitic infection, theretofore not sufficiently active to interfere with the process of calcification, is most intense at the fourth month after birth; (Fig. 5) calcification of the deciduous teeth having already taken place no evidence of syphilis will be seen upon them. But, because at this time only about half the crowns of the incisor teeth have undergone dentinification, the stigmata will, after their eruption be evident on them, at the same level, viz., about half way up, on the crowns

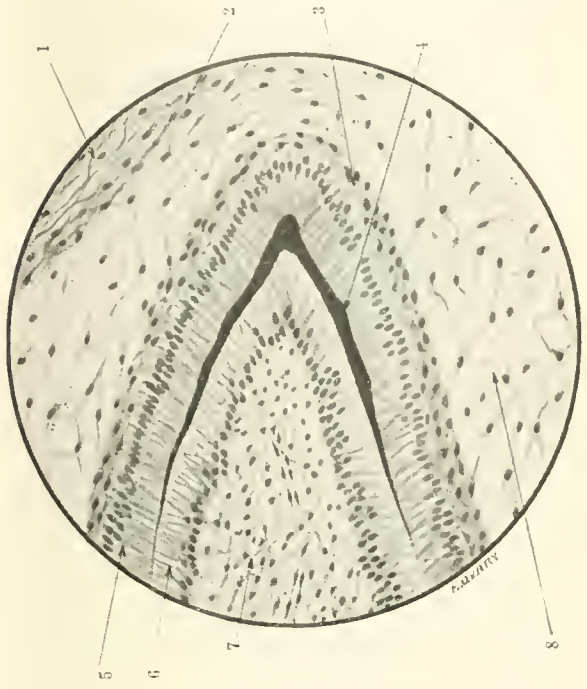

Fig. 3.—Higher magnification of the contents of the circle in Fig. 2. Notice that the enamel has not begun to form. (Leitz, oc. IV, obj. 5.) 1. Dental sac; 2. outer layer of enamel organ; 3. stratum intermedium; 4. dentin cap; 5. inner layer of enamel organ; 6. odontoblasts; 7. dentinal papilla; 8. palate reticulum.

of all the eight incisor teeth. Dentinification for the cuspid teeth is beginning at this same period, consequently only the summit of these four teeth will be affected. The first and second bicuspids will not be affected at this time as dentinification has not yet begun. But the first molar teeth at the fourth month after birth have considerable dentine (half or two-thirds) formed for the crowns of their teeth, consequently the lesions will appear about half or two-thirds the way up, on the crowns of those teeth.

The second and third molar teeth cannot be affected as dentinification does not occur until some years later.

The stigmata of developmental syphilitic hypoplasia are usually found upon the same group of teeth at about the same level on their crowns.

Some general morbid influence produces the hy-

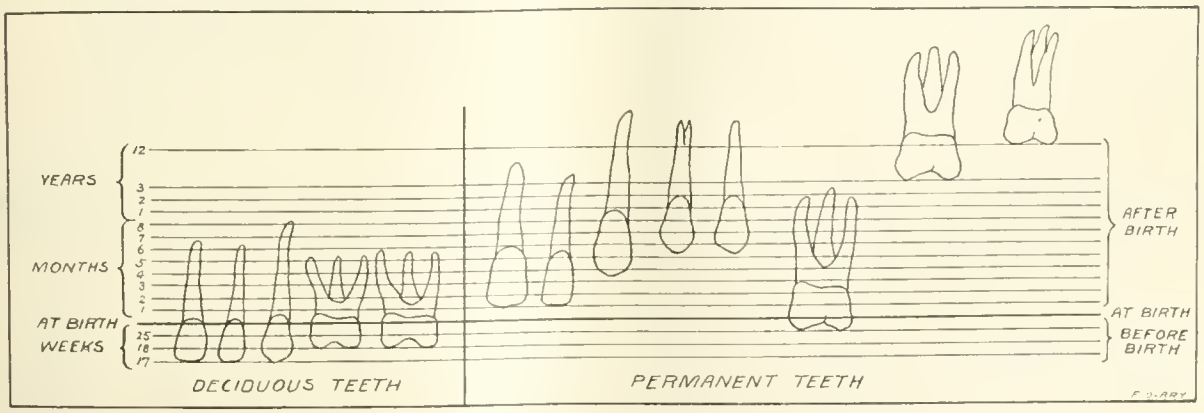

Fig. 4.—The time of the inception of calcification (dentinification) of the teeth.

poplasia for a local cause would produce a more or less local result, *e. g.* an osteoperiostitis of the left half of the mandible might interfere with the development of the teeth on that side but not upon the other side nor with teeth of the maxillæ.

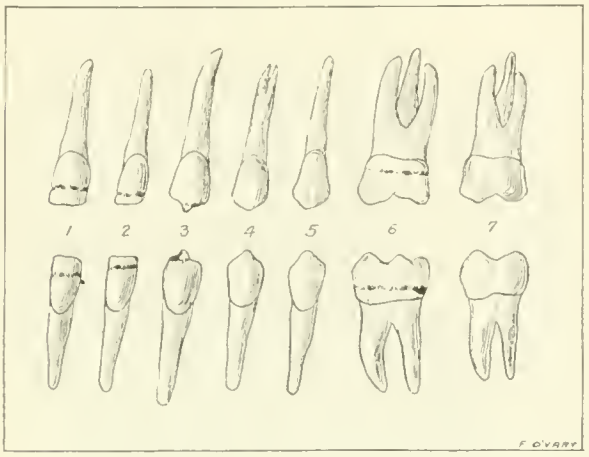

FIG. 5.—A semi-diagrammatic representation of a systematized hypoplasia of several sorts of upper and lower teeth (incisors, cuspids, and molars). The general systemic disturbance which must have caused these stigmata occurred about the fourth month after birth. (The third molars have not been inserted in the drawings.)

A local cause cannot produce, but a disturbance in metabolism occasioned by the severe general systemic syphilitic infection of the embryo, fetus, or young child could produce: (1) Multiple and disseminated stigmata of the teeth in both maxillæ and mandible. (2) Symmetrical stigmata here and there upon homologous teeth. (3) Systematized stigmata at the same level on different sorts of teeth.

The most characteristic stigmata of the teeth in heredosyphilis are: (1) Hutchinson's teeth; (2) Hypoplasia of the morsal surface of the incisor teeth, other than Hutchinson's teeth; (3) Hypoplasia of the morsal surface of the cuspid teeth; (4) Hypoplasia of the facial, lingual, and mesial surfaces of the teeth in the form of pits, furrows

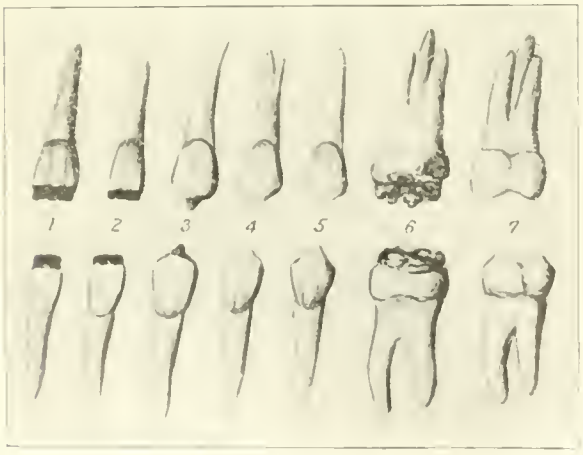

FIG. 6.—A semi-diagrammatic representation of a systematized hypoplasia of several sorts of upper and lower teeth (incisors, cuspids, and molars). The general systemic disturbances which must have caused these stigmata commenced about the twenty-fifth week of intra-uterine life and continued up to about the fourth month after birth. (The third molars have been omitted.)

and honeycombed teeth; (5) Symmetrical hypoplasia of the four first molars; (6) A systematized hypoplasia of several sorts of upper and lower teeth, *e. g.* incisors, cuspids and molars.

Hutchinson's Teeth.—Jonathan Hutchinson was the first to describe this extraordinary dental stigma and explain its pathological significance. This form of syphilitic dental hypoplasia, which was the first recognized, is characterized in its most typical form by a marked crescentic indentation of

FIG. 7.—Typical Hutchinson teeth. (Fournier.)

the morsal surfaces of the two upper median incisor teeth (Fig. 7). The term Hutchinson's teeth has been misapplied to any other tooth having a similar depression upon its morsal surface. This form of hypoplasia has also been seen in heredosyphilitics upon the four inferior incisor teeth and even upon cuspid teeth.

According to Hutchinson this term is to be applied to the superior central incisor teeth of the second dentition presenting a semilunar depression on their morsal surfaces, the teeth being screwdriver shaped (wider at their neck and narrowing towards their morsal surfaces) and converging obliquely. (Figs. 7 and 8.)

This lesion when typical has such an individuality that no other dental lesion can be confused with it. It can be recognized at a glance. It is impossible to misunderstand it, although it varies in character with the age of the heredosyphilitic. When the tooth erupts the characteristic semilunar indentation upon its morsal surface does not exist. The place where the future crescent is to form is filled in with hypoplasic tooth structure, either in the form of acuminate buds, points, or spicules forming a sort of fine denticulation, or in the form of a more or less homogeneous lobular mass. This hypoplasic dentine, which is not covered with enamel, is non-resistant, friable, and rapidly crumbles and wears away so that after a few years it entirely disappears and in its place we have the crescentic notch.

During adolescence the morsal surfaces of Hutchinson's teeth change and at maturity lose their

FIG. 8.—Typical Hutchinson teeth in a patient twenty-two years of age. Here the crescents have nearly disappeared, but the beveling on the facial surface of the teeth is still evident. Notice the pits on these teeth, especially the upper left central incisor. The cause of this patient's condition, facial paralysis, was first recognized through these two upper central incisors. His blood afforded a positive Wassermann (N. Y. Health Dept.) reaction, and examination of his eyes revealed a heredosyphilitic choroiditis.

characteristic appearance. The arcs on these morsal surfaces gradually diminish; at 20 to 22 years (Fig. 8) they are noticeably effaced, and at about the twenty-fifth year the characteristic crescents disappear entirely and the morsal surfaces become

rectilinear. But at the twenty-fifth year an important characteristic of the lesion, the beveling of the inferior facial surfaces of the teeth, still persists; for the crescents of Hutchinson involve not only the morsal surface of the teeth but also

Fig. 9.—An early stage of Hutchinson's teeth, showing the crescents before hypoplasic tooth structure has been worn away. Patient 14 years of age. Mal-coaptation of the teeth.

the facial surface in that the beveling extends from above downwards, slanting from the facial to the lingual surface of the teeth, and so involving more of their facial surface. These bevels which crown the crescentic notches are the last of the stigmata to be effaced through usage of the teeth and they are the last vestige of Hutchinson's teeth, disappearing at about the thirtieth year. The teeth then are shorter and have lost all their diagnostic significance.

The so-called "crescentic notch of Hutchinson" may also be seen upon the following permanent teeth: (1) The lateral superior incisors; (2) All the lower incisors; (3) Very exceptionally upon the cuspids.

Legros, Hutchinson, Moon, and Fournier report having seen Hutchinson's crescent upon one upper central incisor tooth, the other being perfectly normal.

The superior incisor teeth, especially the central incisors may have the screw-driver shape, but neither converge nor have they crescentic notches upon their morsal surfaces. This lesion is at times so slight that it is liable to be overlooked. Such teeth have not been conclusively shown to be of heredosyphilitic origin.

Hutchinson's triad, viz., Hutchinson's teeth, in-

Fig. 10.—Teeth of heredosyphilitic (?), eleven years of age. Hypoplasic flattening of the morsal surfaces of the upper central incisors, hypoplasia of cuspids, amorphism of teeth. Absence of upper right lateral incisor. Patient had a hypoplasia of the morsal surfaces of the first molars, more or less general venous ectasia, general infantilism, a high and contracted dental arch, general adenopathy, and had undergone two operations for adenoids. Wassermann negative (N. Y. Health Dept.).

terstitial keratitis, and otitis media, are pathognomonic of heredosyphilis.

Hypoplasia of the Morsal Surfaces of the Incisor Teeth other than Hutchinson's Teeth.—Among the numerous forms of hypoplasia of the morsal surfaces of the incisor teeth the following are the most frequent types: (1) *Flattened;* (2) *Saw-like;* (3) *Stunted.*

In the flattened type the summit of the tooth is flattened on its facial and lingual surfaces, resem-

Fig. 11.—This case shows pits on the teeth, saw teeth, hypoplasia of morsal surfaces of the upper lateral and all the lower incisors and upper left cuspid, and microdontism and amorphism of teeth. The patient was thirteen years of age, and but 4 ft. 1 in. in height, showing all the signs of general infantilism, and a persistence of the deciduous upper second molars, hypoplasia of the two upper and loss of the two lower first molars, and delayed dentition of three second molars, a heredosyphilitic choroiditis, and a positive Wassermann (by N. Y. Health Dept.) reaction.

bling somewhat a tooth which had the summit of its crown compressed on its four sides in a vise (Fig. 10). This hypoplasic surface appears yellow, gray, or even black at some points and is irregular, uneven, and roughened with more or less vertical furrows. I have seen cases where this stigma extended on the crown of the tooth to the height of 3 mm. from the morsal surface. It is evident that this portion of the teeth is friable and easily falls to pieces. Fournier compares it to "a sheet of heavy paper."

The "saw-like teeth" (Figs. 11-13) have morsal surfaces which are irregular and rugged as if fine vertical incisions or little grooves had been filed on them.

The teeth with "stunted" morsal surfaces have circular grooves about 2 or 3 mm. from their summits, from which emerge amorphous yellowish caps. Sometimes these caps appear like small teeth placed upon larger ones; at other times the caps have small buds upon their summit giving the caps the appearance of a clove, "stunted" teeth with such caps are sometimes called "clove teeth."

Hypoplasia of the Morsal Surface of the Cuspid Teeth.—Syphilitic hypoplasia of the cuspid teeth occurs nearer the morsal than gingival margin of these teeth. A circular constriction is evident near their morsal surface, the hypoplasia portion ap-

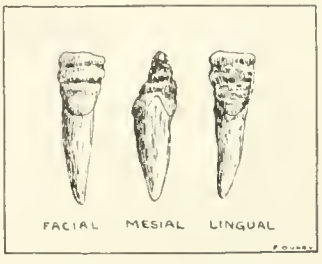

Fig. 12.—Typical syphilitic stigmata in the form of transversely arranged furrows and pits on the facial, mesial, and lingual surfaces of incisors.

pearing somewhat like a teat upon the end of the tooth.

Hypoplasia of the Facial, Lingual, and Mesial Surfaces of the Teeth in the Form of Pits and Furrows, and Honey-combed Teeth.—The pits in the

teeth vary in size, they may be very small like the depression made in soft wax with the point of a pin or they may be large, deep and similar to a depression made in soft wax with the head of a match. The surface of these pits is irregular and in young

Fig. 13.—See legend of Fig. 15.

teeth is white, but later becomes gray, brown or even black. These pits varying in depth, may be very superficial with a slight covering of enamel, or may extend a considerable distance into the dentine (Figs. 8-11). They involve by preference the incisors, especially the central superior incisors. They vary in number and where several exist they are usually disseminated without order, but at times they are arranged in a horizontal line and more rarely in two superimposed horizontal lines separated from each other by one or two millimeters.

Stigmata in the form of furrows are more common than pits upon the crowns of teeth. The tooth appears as if it had been scratched transversely and the scratch, furrow, or sulcus encircles the tooth horizontally.

The furrow may be so superficial that it is likely to escape notice and resembles a line on a sheet of paper made by the pressure of one's finger nail. This lesion, which is not very evident, gives one the

Fig. 14.—See legend of Fig. 15.

impression that it is a transverse line, not a groove, crossing the tooth. The existence of the groove, however, is proved by scratching the crown of the tooth with the finger nail. Sometimes the groove may be a quarter to one-half a millimeter deep with little or no enamel covering. This form of lesion later becomes gray or black and so more striking and evident.

Instead of the stigma taking the form of a single groove traversing the circumference of the tooth horizontally, there may be two, three or more of them (Fig. 12). The multiple grooves which are superimposed horizontally on the crowns of the teeth are located nearer the morsal surface than gingival margin of the tooth. The grooves are separated by bands of enamel which form light ridges between them. Such teeth have been called by the French "dents en étage, dents en escalier, or dents en gradin." We might call them "graded" or "intermittently affected teeth." The grooves, alternating with the ridges, indicate alternating periods of exacerbations and remissions of the disease.

The morsal surface of such teeth where the first grade or step of the hypoplasia appears is usually thin, rough, irregular, brownish in color and without any enamel covering. It rapidly falls to pieces and disappears so that in adolescence or in young

Figs. 13, 14, and 15 are taken from casts showing the teeth of a heredosyphilitic, thirteen years of age, whose father, mother, sister, and two brothers were also syphilitic, all giving a positive Wassermann (by Otto Lowy, Newark, N. J.) reaction excepting the youngest brother (two months of age). An examination of his blood was not made because the *Treponema pallidum* was found by me under the dark field microscope in the exudate taken from the mucous patches about his mouth. This case shows delayed dentition, hypoplasia of three of the first molars (the left upper first molar not having erupted), persistence of all the deciduous molars in the mandible and the second deciduous molars in the maxilla, a saw tooth, microdontism, amorphism of teeth, Hutchinson's crescents on the upper lateral incisors, and malcoaptation of the teeth.

adult life the tooth is deprived of its morsal surface and the shortened crown of the tooth appears as if this morsal surface had been cut off transversely.

Stigmata in the form of furrows usually appear on the incisor teeth but they may appear upon the cuspids or first molars.

Sometimes a third, a half, or three-fourths of the crown of the tooth is hypoplasic, so that its surface is uneven, rough and at times anfractuous, and appears grayish yellow, even grayish black. Fournier calls such a lesion "erosion en nappe." Tomes calls the teeth "honey-combed teeth."

Symmetrical Hypoplasia of the Four Permanent First Molar Teeth.—The morsal surface of the four permanent first molar teeth is completely changed (Fig. 6). In infancy and adolescence two-thirds or three-quarters of each tooth nearer its morsal surface is hypoplasic, diminished in all its diameters, eaten away, and marked off

from the rest of the tooth by a circular constriction; so that there appears to be a small stump-like tooth, a stump of undeveloped dentine, emerging from the remaining apparently normal crown. This surface is extremely irregular with rough, conical, pointed eminences which are at times markedly anfractuous, has fissures which are more or less deep, and penetrate even the dentine, and has a yellow, brown, dirty gray, or black appearance. This hypoplasic stump partially covered with enamel is gradually worn away and crumbles to pieces so that it finally disappears and with the crown of the tooth thus shortened, the morsal surface becomes flat, yellow in color and surrounded by a zone of white enamel. *This symmetrical hypoplasia of the morsal surfaces of the four permanent first molar teeth is of the greatest importance in the diagnosis of heredosyphilis.*

Later on caries attacks the central portion of the morsal surface of these teeth, frequently destroying them. Thus, the heredosyphilitic may have either a hypoplasia of the crowns of his first molar teeth or caries at the center of the remainder of the crowns of three or four of his molar teeth, or a loss of some or all of his first molar teeth through caries, or a combination of these conditions.

The hypoplasia of the morsal surfaces of these first molar teeth, which must have begun at some time after the beginning of the sixth month of intrauterine life, proves that the fetus has been attacked by some disease at this time, and syphilis appears to be this disease.

I quote from "Diseases of the Mouth" (F. Zinsser—J. B. Stein): "On the facial surfaces of all the upper and lower incisor and cuspid teeth are several furrows and cuplike erosions, and all their morsal surfaces are notched in several places. All the first molars are missing except the lower right one, in which there is a central caries, apparently following a developmental hypoplasia of the morsal surface. The cuspid and bicuspid teeth show on their surfaces slight erosions and transverse furrows. This is the result of a condition existing before birth and continuing to the end of the first part of the second year of life. The history of this case is very instructive."

"The patient, a boy of twelve years of age, had been treated a year and a half for a parenchymatous keratitis. The diagnosis of syphilis was not made, and antisyphilitic treatment was not energetically applied because the keratitis did not react well to mercury. The Wassermann reaction was negative, there were no other symptoms of heredosyphilis, and the condition of the teeth was attributed by me (Zinsser) at that time to rhachitis. A year later the boy returned with a severe syphilitic perforation of the hard palate and a positive Wassermann reaction. If the hypoplasia of the lower right first molar had been recognized as a sign of heredosyphilis and energetic antisyphilitic treatment resorted to, the patient would have been spared the severe disfigurement."

A Systematized Hypoplasia of Several Sorts of Upper and Lower Teeth.—This form of hypoplasia affects several sorts of teeth; the teeth of one sort at one level and those of another sort at another level. The hypoplasia is multiple, being as a rule found on (1) All the incisor teeth (superior and inferior). (2) All the cuspids (superior and inferior. (3) All the first molars (superior and inferior). It does not seem to affect the bicuspids or second and third molar teeth.

Dental infantilism.—Delayed dentition, microdentism and persistence of the deciduous teeth may serve as a stigma of heredosyphilis. Microdentism of all teeth is rare, but a number of teeth—mostly the superior and inferior incisors—and occasionally single teeth exhibit this condition (Figs. 13, 14, and 15).

The so-called *persistence of the deciduous teeth, i. e.*, their non-replacement by the permanent teeth occurs more frequently than is generally supposed (Fig. 14-15)—in one-third of the cases of heredosyphilis, according to one observer (Chompret). Few physicians or dentists have recognized this condition in heredosyphilis. It is a very important diagnostic sign. The deciduous teeth which remain in the mouth for a longer time than is usual are in order of frequency, the following:—(1) the second molars; (2) the first molars; (3) the cuspids; (4) the incisors.

The persistence of the deciduous tooth appears to be due to the absence or arrested development in the tooth which should displace it.

Absence of Certain Teeth, etc.—The absence of certain teeth is a stigma which occurs in heredosyphilis implying a non-formation or complete arrest in development of the dentinal germ or follicle.

Abnormalities in the position of teeth and amorphism of the teeth (Fig. 13) (teeth with crowns somewhat resembling sharks teeth, pianokeys, pebbles, squares, twisted teeth, pegged-shaped teeth, etc) are frequently attributed to heredosyphilis and less frequently, the following conditions, viz., (1) Vulnerability of the teeth and marked liability of the teeth to caries resulting in premature edentation. (2) Malcoaptation of the teeth, or, as Fournier called it "the absence of the sign of the artichoke" (Fig. 13). (3) Asymmetry of the superior maxillary bones. Prognathism and deformities of the lip and palate. (4) The presence of supernumerary teeth.

Some forms of hypoplasia of the teeth are certainly syphilitic, and some may be attributed to syphilis but there are forms of hypoplasia of the teeth which are certainly not caused by syphilis.

Non-syphilitic hypoplasia of the teeth has been seen in animals (the bull and very frequently the dog).

Fournier found that of 480 cases of heredosyphilis examined by him approximately 43 per cent displayed hypoplasia of the teeth as marked stigmata of the disease.

Many patients with hypoplastic teeth have been seen by me whose blood has given a negative Wassermann reaction. This does not disprove the syphilitic nature of the hypoplasia because the syphilis may have been cured or arrested. Some of our patients with hypoplasia of the teeth whose blood gave at first either a negative or a weak positive Wassermann reaction gave later a distinct positive Wassermann reaction. The luetin reaction of Noguchi, which he and others claim is valuable in detecting heredosyphilis, may be useful in confirming the diagnosis of syphilis in cases where dental stigmata exist.

Hypoplasia may affect the teeth at hazard and without method, depending upon some local accident or affection, and apparently has no significance or its significance is at present unknown. But the hypoplasia which I have described either affects symmetrically certain sorts of teeth (the first molars or incisors especially, the two upper central

incisors) or affects several sorts of upper and lower teeth, *e. g.*, the incisors, cuspids, and first molars, in a more or less systematized way.

There must be some general morbid cause for these conditions. Morbid conditions other than syphilis, can produce hypoplasia of the teeth, but the hypoplasia thus produced is not the same as that caused by syphilis, and *vice versa*. Of all diseases, syphilis is the most frequent cause of hypoplasia of the teeth (80 per cent of the cases according to Fournier). Heredosyphilis is essentially a dystrophic disease and exercises its noxious influence especially during intrauterine life and the first months after birth, at a time when dentinification is beginning or progressing.

What diseases are met with in intrauterine and the first months of extrauterine life which would profoundly affect the cells of the entire organism and the cells of the dentinal germs in particular? Rachitis rarely occurs during the first six months of life; usually in the second year. To-day variola is seldom met with. Scarletina, measles, diphtheria and typhoid fever are rarely observed during the first year of life. Acute rheumatic fever seldom occurs before the fifth year; and can it be said that a disturbance in metabolism occasioned by gastroenteritis could cause hypoplasia of the morsal surfaces of the first molar teeth?

Has an authentic case been recorded either of a symmetrical hypoplasia of the crowns of the four molars, or of Hutchinson's teeth, or of a systematized hypoplasia of several sorts of teeth, upper and lower, which was caused by any disease other than syphilis?

Heredosyphilis appears to be the only cause of these three forms of hypoplasia of the teeth, and until some better proof is forthcoming must be regarded as the definite cause.

The diagnostic significance of syphilitic dental stigmata is of great importance:

1. In detecting heredosyphilis; because the stigmata are at times the only evidences of this disease.
2. In tracing, in a patient with these stigmata, the possible syphilitic origin of some condition the cause of which was unknown and was not suspected of being syphilitic.
3. In tracing back the existence of syphilis, as, for example, in diagnosing the condition of a woman (the mother of a child when she has no manifestations and gives no history of the disease), an examination of her children's teeth may prove her to have had syphilis; and so in diagnosing a younger child's condition (an epileptic for example) the examination of an older brother's or sister's teeth may alone reveal or lead to a discovery of the diseased syphilitic condition through which the younger had passed.
4. In life insurance examinations.
5. In the effective administration of the efforts of all interested in dental, oral, social, moral, and mental hygiene.

205 East Twenty-third Street.

The Speech in Athetosis.—W. B. Swift relates a case of athetosis which shows in the vocal mechanism as a constant intertwining change of mouth positions, so that all sounds are immediately varied into other forms of vowels and other sounds of consonants; their interrelations are extremely varied. In brief, athetoid speech is a constant variation in vowel form and consonant sound, clear only when correctly struck during the constantly changing contractions or when, during rare moments of relaxation, the sounds are hit before contractions occur.—*Review of Neurology and Psychiatry.*

PRIMARY CARCINOMA OF THE LUNGS

By ERNEST SCOTT, M.D.,
Professor of Pathology, Ohio State University,
and
JONATHAN FORMAN, M.D.,
Columbus, Ohio.
(From the Department of Pathology of the Ohio State University.)

Increased interest in primary carcinoma of the lung in recent years has furnished statistics which indicate that this condition is more frequent than is usually stated. Reinhardt, in 545 cases of carcinoma, found five which were primary in the lung. Passler recorded 16 cases in 1000 cases of carcinoma. In the course of 16,047 autopsies in one of the large hospitals of Petrograd during the last ten years, primary carcinoma of the lungs is reported by Laurinovich as having been found sixty-one times, or 0.38 per cent. In the laboratory of pathology at the Ohio State University, three primary pulmonary carcinomata were chanced upon, while 302 carcinoma were being collected.

A summation of the more recent statistics made by Weller, in 1913, gave an incidence of 0.3 per cent in 11,093 autopsies. In the same year, von Wiczkowski compiled the reports of 126 cases in 58,497 autopsies.

In 1912, Adler published his excellent monograph, in which he gave the reports of 374 collected cases of primary pulmonary carcinoma. In 1913, Weller

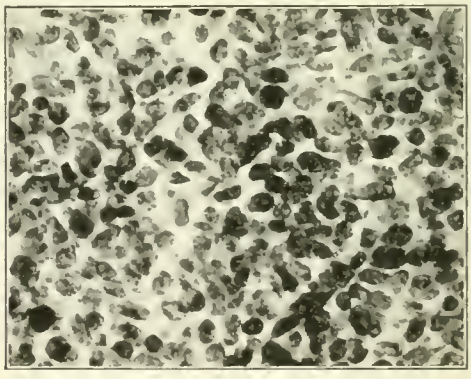

Fig. 1.—The type of cells seen in the more undifferentiated areas of cases I, II, and III.

published a collection of the primary carcinoma of the larger bronchi. His series contained nineteen cases not mentioned by Adler, including his own case. In 1912, there were seventeen other cases reported, one each by Apert and Rouillard, Gilchrist, Pfister, and Edlavitch, together with 13 cases by Kolszewski. In 1913, von Wiczkowski added six cases, Lombardo and Argaud, Crespin, and Legroux two cases. In 1914, Leclerc and Michel reported a case, and Edlavitch added his second case. In 1915, the paper of Laurinovich, based upon sixty-one cases, appeared, and in 1916 Herrman and Mayer report a single case.

There are not doubt many other cases which have been reported but are buried in papers bearing upon some other phase of work. As examples of this, there is the brief report of a case by Ash, in a discussion of the pathology of mistaken diagnosis in the Consumptive Hospital, and also the case described by Howard and Schultz in their monograph on the biology of tumor cells.

In lower animals, primary tumors of the lung are rather frequent. Tyszer, who first called attention

to the frequency of neoplasmata of the lungs in mice, found fifty-two lung tumors in seventy mice, which had developed eighty-three spontaneous tumors, or 62 per cent. of the total. Slye quotes Sticker that, in 1026 cancers in horses, cattle, dogs, sheep, cats and pigs, 3 per cent. were primary in the lungs. In her own series of 6000 autopsies upon mice, Miss Slye found that 1 per cent. of the series presented primary malignant tumors of the lungs.

This paper is a study of four specimens of primary carcinoma of the lung, which are in the Museum of Pathology at the Ohio State University.

Case VI, however, is of the dermoid type, and presents a different picture. In this case, the lung is small and firmly bound in with adhesions. A mass measuring 5 x 6 cm. in cross section occupies the upper lobe, and attaches itself to the ascending and transverse portion of the arch of the aorta involving the bronchial lymph nodes in its growth. The bronchi are completely filled and obliterated by the new growth.

Histological examination shows a tumor composed of squamous epithelial cells, which present intercellular bridges and a concentric arrangement

Case	Age, Sex, Occupation	Lung Involved	Clinical Symptoms	Sputum	Remarks
I. 1246.	Male. 60. Broker.	R.	"Dulla che" in right chest for last year. Attacks of violent coughing during last 18 months. Distinct shortness of breath for 6 months. Slight irregular fever. Areas of consolidation in right lung. Marked cachexia.	Muco-purulent and rather abundant. Neg. to tuberculosis.	Diagnosis: Tuberculosis. Autopsy by Dr. Scott.
II. 2129.	Male. 48. Salesman	R.	Began with attacks of violent coughing and sharp pain in right chest. Treated in sanitorium for tuberculosis. Pleural cavity tapped and then rib resected both with negative results. Evidences of consolidation in right lung. Marked orthopnea. At the end swallowing became nearly impossible. Patient lost 50 pounds in all.	Muco-purulent. Negative upon repeated examination for tubercle bacilli.	Diagnosis: Tuberculosis. Autopsy by Dr. Scott.
III. 2574.	Male. 60. Manufacturer.	L.	Two years previously patient caught in a belt and suffered severe contusion to right chest wall. From this time on, a dry hacking cough developed. During the last few months, slight dyspnea and a slight, irregular fever B. C. (shortly before death) 15,000 leucocytes with 85 per cent polymorphonuclears.	Small in amount.	Seen by many physicians who made a diagnosis of tuberculosis. Last one diagnosed a cancer of lung. Autopsy by Dr. Barnes.
IV. 2568.	Male. 50. Chemist in smelting works	L.	Began as a "bronchitis" with a constant dull pain in the left chest. Followed by cough paroxysmal and very severe in character. Slight, irregular increase in temperature. Towards the end swallowing became somewhat difficult.	Abundant and muco-purulent. 15 examinations negative for tuberculosis.	Diagnosis: Tuberculosis. Autopsy by Dr. Scott.

The important features of the clinical notes are given in the accompanying table. It is interesting to note that, based upon a slight increase in temperature, the presence of a cough, evidence of consolidation in the lung and the loss of flesh, each case was mistaken for one of pulmonary tuberculosis in an advanced stage.

Complete autopsies were held in each instance, and no new growths were found other than in the lung.

There is a striking similarity in Cases I, II and III. The new growth in each instance begins in the large bronchus at the root of the lung, and extends along it into the substance of the lung. In each case, the growth consists of a yellowish mass in which remnants of bronchi may be seen. In Case I, the upper lobe is chiefly involved. In Case II, the tumor occupies the middle lobe and the upper portion of the lower lob, while in Case III the lower lobe is involved exclusively. In all three cases, the bronchial lymph nodes have been invaded and overgrown by the neoplasm. The growth has extended into the pericardium in Cases I and II. In Case II, there is also a distinct invasion of the esophagus producing stricture. In each lung there is a thickening of the pleura, which is especially marked over the portion of the lung involved by the tumor.

The histological pictures presented by the first three specimens is also very similar, varying with the portion of lung examined. Sections taken from the roots of the lungs, and including the wall of the larger bronchi, show masses of large cells which are definitely epithelial in type. Sections of the esophagus at the constriction in Case II show that this stricture is due to an invasion by the tumor cells rather than to a primary growth. Sections taken from the main mass of the tumors present cells which have lost their distinctly epithelial character and have become small in size and irregular in shape, and appear when taken by themselves not unlike those from certain sarcomas. They, however, resemble somewhat the cells seen in the basal layer of normal bronchial epithelium. with keratinized centers. Karyokinesis is abundant throughout the tumor. In certain areas, especially from those in the outer border of the cell masses, ten or more mitotic figures may be seen in almost every field presented in the use of a 16 mm. objective.

It is of further interest to note in Case IV that a branch of the tenth nerve is markedly infiltrated with cancer cells. This patient had suffered constantly from pain in this region. The need of more investigation into the relationship between pain in carcinoma and the invasion of the nerves has recently been emphasized. As regards this feature of primary carcinoma of the lungs, Kretschmer noted the involvement of the left vagus, and Passler reported extension into the "larger nerves."

In lower animals metastasis outside of the lung substance is not common. In her series of mice, Miss Slye reported four cases of metastasis in pulmonary carcinoma. In Adler's series of 374 human cases, metastasis is mentioned 280 times. In none of the four cases here reported do nodules appear, which do not have continuity with the primary tumor.

In two of these cases (III and IV), mitosis is a conspicuous part of the histological picture. Henrici in his case mentioned the presence of cell division. Howard and Schultz noted the mitotic figures in their case. Miss Slye noted that she had never seen a lung tumor in which the mitotic nuclei were not difficult to find. In relation to the etiology, it is interesting to note that there is only a moderate amount of anthracosis in each of these cases. Pigmentation, therefore, would not appear to play an important etiological role here.

In Case IV, the patient had been subjected for years to the influence of heavy tobacco and strong chemical vapors. This exposure might easily be considered as an exciting factor, the more especially when the epidermoid character of the tumor is considered.

Grosser injuries have long been considered as causative factors in the production of carcinoma. Adler, in his series of lung carcinoma, found that in only six of the 374 cases was traumatism in the ordinary larger sense recorded. So as an important etiologic factor this can be eliminated. Gross injury is recorded in only one of this series. In Case III, it is noted that the contusion was done to the right side of the chest, and that the cancer developed in the left lung, thus making an etiological relationship quite improbable.

As to the probable origin in each instance, it is to be noted that there is a distinct invasive growth within the lumen of the bronchus. In two Cases (III and IV), the growth in the upper portion of the bronchus extends for a considerable distance unaccompanied by any peribronchial growth whatever. Further in each case, there is direct continuity of the growth in the lumen with that in the lung substance.

In Cases I, II and III, it is difficult to determine the exact histogensis from the microscopical evidence alone. This is not at all remarkable when the continuity and embryological identity of the bronchial and alveolar epithelium is taken into consideration. Cuboidal and rather high columnar types of cells may arise from either of these locations.

In these cases the tendency to undergo a more complete differentiation exhibits itself in the growth within the bronchus. Here quite high columnar cells may be seen. As the tumor cells are followed out into the lung substance, they lose their differentiation. First, they come to resemble cells of the fusiform type seen in the normal bronchial epithelium. Then they pass over into a type of small irregular cells which are not unlike those of a basal layer of the mucosa. In some areas all differentiation is lost, and the cell presents itself as a small round cell with scant cytoplasm and a small deeply staining nucleus. These cells so closely simulate the cell type seen in undifferenciated rapidly growing sarcomata that a mistaken diagnosis might easily be made had not sections been taken from the bronchus.

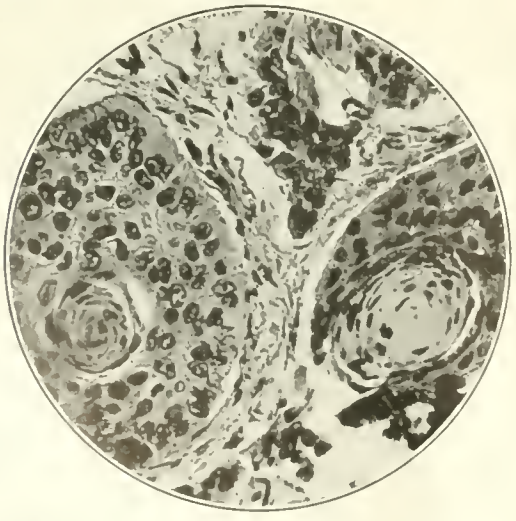

Fig. 2.—The formation of keratinized whorls in case IV.

Alveolar epithelium may, it is true, be transformed into a columnar type, but in no instance do any of these cells present an apparent attempt to resemble the large flat cells of normal alveolar epithelium. There is not a papillary formation seen such as Miss Slye and others have noted in mouse cancers. There are considered by her as probably of alveolar origin. In all of this series the air sacs are invaded and filled by tumor cells, presenting much the same picture as that described

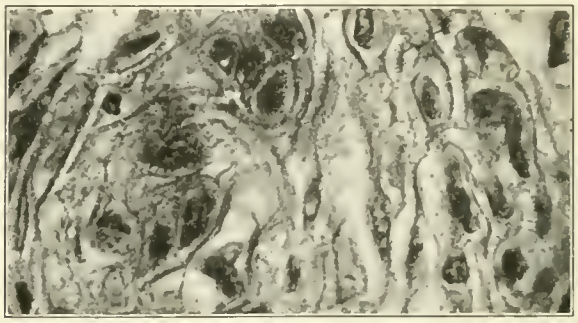

Fig. 3.—The intercellular bridges developed by the cells of the carcinoma in case IV.

by Henrici in his case, where the tumor cells were using the alveolar wall for their stroma.

While these data are not convincing evidence as to the bronchial origin, it is very suggestive of such an origin, especially when the gross features of the specimens are taken into account. Mitotic nuclei were not difficult to find.

As to Case IV, the evidence is somewhat cleared. As Henrici observes, "it is a far cry from simple aveolar epithelium to a structure composed of stratified squamous cells, having inter-cellular bridges, forming types of epithelial pearls, and in some instances keratin." Several observers have noted metaplastic change to a squamous type of epithelium on the part of the bronchial mucosa in the absence of tumor formation. Haythorn reported this observation in three cases of pneumonia. He considers these metaplastic cells as newly formed from the growing layer in an attempt at repair. In Case IV, there is a distinct history of prolonged irritation to the bronchial mucosa and the epithelium of the bronchi, where it is not involved in the new growth, presents many areas of metaplasia to a distinctly flattened type of cell, so that this case would seem to bear out Haythorn's conception. These facts, together with the gross features of this case, make a bronchial origin quite probable.

Conclusions.—1. The fact that Adler was able to collect only 374 authentic cases of primary carcinoma of the lung from the literature up to 1912, and that at least 120 cases have been reported since, makes it apparent that the condition is much more frequent than the earlier statistics would indicate.

2. A study of these cases tends to confirm the idea that the majority of the so-called primary carcinoma of the lungs are probably in reality of bronchial origin.

3. A casual histological examination may lead to a diagnosis of sarcoma in certain cases of carcinomata of the lungs.

Acknowledgement is due for the clinical notes on Cases I, II and IV to Doctors Horton, Edmiston and Deem, in whose practice these cases respectively occured. We are also obligated to Dr. Robert L. Barnes for the presentation to the Museum of the specimen in Case III, together with the clinical notes and for permission to report the case.

GASTRO-ENTEROLOGY AND SURGERY.

By J. C. JOHNSON, M.D.,

ATLANTA, GA.

Ordinarily the matter which I wish to discuss would not be entitled to a place in a program devoted to purely scientific subjects. But I think that it is as vital as any before the profession and that it deserves special mention at this time.

I refer to the increasing tendency, on the part of some, to magnify the importance of surgery and to minimize the importance of internal medicine in the treatment of gastrointestinal diseases. Quite a number of our leading surgeons have expressed the opinion that more than 90 per cent of gastrointestinal diseases are primarily surgical, while others, with the same meaning, say that primary disease of the alimentary tract is very rare. These expressions have been much quoted, and, the opinions have become convictions in the minds of many.

These opinions are based, of course, upon operations or examinations which revealed some condition associated with indigestion supposed to be without the reach of internal medicine. It appears that no account has been taken of the majority of patients with gastrointestinal diseases who never apply to a surgeon for treatment, and in whom, presumably, the per cent of surgical cases is relatively small. It is reasonable to suppose that those who have subscribed to this doctrine have considered all the facts involved. Yet, in the light of modern science it is hardly credible that any one can hold views so radical, and, as we believe, so erroneous. It should be remembered that some of these clinicians and writers are accepted as authority in departments of medicine other than those which they so ably represent, and that they speak the last word to a large audience in the wide field of medical practice—that they also have the stronger voice in shaping the policy of under-graduate schools, wherein to a greater extent they direct the thought and inspire the emulation of the students. This departure from our faith in elementary medicine is more significant since we find general practitioners joining in the movement. The possible evil of it is clear. Not all of us, even veterans in practice, are prepared to follow safely in the footsteps of some of those who move along the highest vantage ground. Especially is it impossible for an undergraduate to discriminate between what is established, and what remains in doubt, and to select from the mass before him the essentials he should know. Naturally he learns what is most impressed upon him. And he is impressed more by the objective demonstration of a theory than by the subjective analysis of a fact.

If it is true that primary disease of the alimentary tract is rare, it is also true that much of the medical curriculum is useless. If it is true that more than 90 per cent of gastrointestinal diseases are surgical, the articles of our faith should be revised, and the principles of our practice should be amended. If it is not true that primary disease of the alimentary tract is rare, or that 90 per cent of gastrointestinal diseases are primarily surgical, the profession should not allow this fallacy to stand in the way of progress.

By whom shall these questions be answered, and by what shall the correctness of these answers be

*Read at the annual meeting of the American Gastro-Enterological Association in Washington, May 10, 1916.

judged? Law has its standards, so have art, literature, and other departments of science. What has medicine? Nothing agreed upon but basic principles of organic life. Only by these, therefore, can an impartial decision be rendered in any case.

Opinions may differ, and methods may change, but the laws of organic life do not change. By these laws we have defined the pathology of diseases and have constructed a system of therapeutics. By them have our research efforts been directed and controlled. By them has medicine been elevated from the plane of simple mechanics to the dignity of a more comprehensive science. And they cannot be set aside by any art, however brilliant. I have honestly tried to find some reasonable basis for the contentions of those who are inclined to overlook these facts. But I can see nothing beyond the effect of overzeal on the one hand—of bias and indifference on the other. I confess that I do not know what constitutes a surgical disease. I have heard of infectious disease caused by some infection, of traumatic diseases caused by traumatism. By the same token I can only infer that a surgical disease is one caused by some surgeon. Otherwise, the question remains—whence these diseases? Do they spring like Minerva, full fledged from the head of Jove? Or do they come by way of vital processes, like other diseases—waiting their turn of development and their place in the order of physical change?

The eye of the professional world is riveted upon the alimentary tract and its accessories. There is an insistent cry, especially by surgeons, for the early recognition of diseases common to these parts —which amounts to asking the internist to distinguish by conditions, the pre-existence of which they deny, the character of something the occurrence of which they say is improbable. In other words, the internist is to exercise his skill by watchful waiting, thus automatically opposing the very end which he is expected to hold most conspicuously in view. Despite these contradictions, many are joining in a feverish search for objective symptoms upon which to base a diagnosis. There is not so much thought about what has happened, or about what is happening to give expression to these symptoms. The art of finding out is becoming of more concern than the knowledge of what is found, and what is found is considered of more importance than what produced it.

I do not believe that substantial progress in medicine and surgery is favored by a policy which does not embody every essential principle of medical science, or that any practice, however successful in some particulars, can continue intelligently which does not harmonize every factor related to it. Certainly the future of preventive medicine is not encouraged by depreciation of one department by another.

The newer knowledge of digestion has come hardly less from the laboratory and from the clinical experience of the internist than from the operating room. The internist, therefore, may speak with equal authority of those phenomena most intimately connected with diseases of the digestive system. The channels of our education are too wide and too poorly guarded for us to encourage or condone a weakness within our own system. For this reason it cannot be agreed, even by the assent of silence, that the greatest number of gastrointestinal diseases are either primarily or secondarily surgical. On the contrary, it must be insisted that just the opposite is true. I believe that a brief review of fundamental facts must convince the most doubtful of this. Disease is not an entity—as every well informed physician knows, but a part and product of perverted physiological action. This perversion must start somehow, somewhere and there must be a definite cause for it. Let us find an example in a disease usually classed as surgical. From the standpoint of many surgeons intestinal stasis may be due either to adhesions, atony or kink of the colon. Granting this, and for the time being overlooking the more frequent causes such as errors in diet, abnormal secretion, malnutrition—what is the origin of the atony, adhesions and kinks, and how do they come about?

Something precedes everything. Gallstones do not exist already in the blood and do not precipitate by gravity. Adhesions do not form or reform from mere contact or coincidence. The colon does not kink spontaneously and atony does not develop over night. Gallstones, kinks, and adhesions are neither diseases within themselves nor the primary causes of disease. They are the results thereof. There is no disease which consists of mechanical insufficiency or obstruction alone, or which can be defined by a single circumstance, or limited in its relation to one event. One condition in disease may favor production of another. But the question is what favors production of the first and how and why. This we can only explain by looking from a given effect through a known pathological process to the initial action or a primary cause.

The primary cause of disease is either overwork, underwork, injury, or infection of a part, or of the whole body, as the case may be. Regardless of the cause, the requirements for development are the same. The primary forces engaged in the devlopment are the same. The order of development may vary, and the forces may have different direction, but in essentials of pathology diseases are closely akin—all being the product of perverted metabolism. And when we speak of metabolism we must claim a limitation which does not exist, if we do not in the same connection speak of digestion with its primary importance and possibilities as a causative factor in disease. It is another thing to speak of secondary conditions which jeopardize health or threaten life and the only relief promised is by the knife. But this discrimination has not been made. They say that more than 90 per cent. of gastrointestinal diseases are surgical. They do not say, as it should be said, that no disease is surgical by legitimate birth, but some acquire a surgical nature, while others have it thrust upon them.

Please let it be remembered that we are not discussing what surgery can do, nor even when it should be done—though the latter especially is a question worthy of debate. Surgery has done wonders and promises to do more. And I would not, if I could subtract from the glory of its achevements. Yet the genius of a work consists not in the character or measure of transformation, but in what remains untouched in the accomplishment of the desired result. We believe that some operations have been performed with disadvantage to the patients. On the other hand, surgery is needed in many cases where it is neglected. There are many gall bladders which should be emptied and released and many kinks which should be straightened. Many appendices languish in the iliac vale, unwept, unhonored and unsung, which should have gone the way of their renowned compatriots.

The point is, where can the internist and the surgeon meet, and upon what can they agree. I think the answer is very simple. Unless we are willing to repudiate the laws of biologic and physiological entities upon which such stress is laid by undergraduate medical schools, we must acknowledge their validity and potency in practice. Correct interpretation of these laws allows no divergence of opinion as to their relation in disease as well as in health. According to the laws, if appendicitis can be the primary cause of gastritis, gastritis can be the primary cause of appendicitis. If perverted metabolism can induce myasthenia cardiæ, it can by the same factors lead to myasthenia gastrica, atony, or kink of the colon, and by the same laws and the same factors does primary disorder of digestion result in perverted metabolism.

The same chemicovital and physical forces which preserve a balance of salts in the plasma and substance of the cells, can, when not controlled, become the morbid action anticipating the production of cholelithiasis, or other changes of form or state which we are pleased to call surgical. These are truths which should be emphasized, for they are master keys to many problems which separate us in our ideas and in our efforts.

701 Hurt Building.

THE INADEQUACY OF PRIVATELY-FEED MEDICINE.*

By INEZ C. PHILBRICK, A.M., M.D.,

LINCOLN, NEB.

The history of medical progress records a growing sense of professional inadequacy on the part of profession and laity, and of effort directed toward its correction. Necessarily, in prescientific days, progress was slow. Early acceptance of disease and health as imposed from without by malevolent or beneficent agencies precluded any general development of a sense of personal or professional responsibility for the futilities of the healing art. Nor did empiricism, with its medley of truth and error, offer either incentive or opportunity for the search for new facts. Isolated discoveries of vast moment attested that most valuable attribute of the human mind—scepticism—which in every age has led investigation.

Scientific medicine beginning, in any adequate sense, with the work of Virchow and Pasteur, in the middle of the last century, a time of intense general scientific ferment, has developed synchronously with vastly increased transportation facilities, opening new lands to settlement; the organization of industry on the factory basis, with its outgrowth of occupational disease and accident, and, as a part of the speeding-up policy of competitive industry, its demand for increased efficiency of workers; a change from a rural to an urban environment for nearly one-half of the population; an appalling increase in poverty; and, along with this the growth of the social conscience, which is democracy, demanding for the individual not only the right to live, but the right to health.

Tremendous demands have been put upon medicine. Its adequacy has been tested to the utmost, and found wanting, as attest the various supplementary health agencies to-day in operation, or projected. That medical inadequacy has been more from the art side than from the scientific, from the practical more than from the theoretical, that there has been more of knowledge than of application of that knowledge to human needs, must be ascribed to conditions governing medical practice rather than to any unusual inertia of the medical mind.

Two years ago, in a paper read before this society, I discussed in detail and at length the inherent inadequacy of privately-feed medicine, the determining principle in this inadequacy being competition. It has seemed to me of value to consider at this time the various supplementary health agencies already in operation or planned, to determine if they be free from or exhibit the evils and weaknesses characterizing privately-feed medicine, and, if they utilize those methods imposed by modern conditions.

The past few decades have revolutionized knowledge of the causation of disease and of means necessary to its cure. To-day are demanded as routine procedures diagnostic methods which require much time, expensive equipment, accuracy of technical knowledge, delicacy of manipulation, trained interpretation. Present demand is for a highly organized system of medical practice, with minute specialization, limitation of function and cooperation. Contrariwise, present practice is still in theory on the ameba plan, presupposing the ability of any part of the medical mass, equally with any other, to procure, assimilate, and make contact with the environment. No physician to-day can acquire, assimilate, and apply to the prevention, diagnosis, and cure of disease any considerable part of medical knowledge. Nor can he command facilities for efficient work.

The other day, in cleaning my attic, I was strikingly reminded of the enforced changes in my practice in two decades; and I am certain my experience has not been exceptional. Unopened vials of tropæolin, congo red, methyl violet, Canada balsam; a number of Levis' perforated metal splints; Thoma-Zeiss hemacytometer and von Fleischl hemaglobinometer; silver chloride dry cell and acid cell galvanic batteries, etc., recalled the days when I, not from choice, but of necessity, to eke out income, in my inadept way, stained and mounted specimens, treated fractures, counted red and white blood cells, and estimated hemoglobin other than by the Talquist paper, and had not relegated the use of the electric current to the electrotherapeutist, who alone can develop and bring to bear its therapeutic virtues. My office table, as I am sure does that of most general practitioners, bears witness to the abandonment of the attempt to more than keep abreast in a general way of medical progress. Two general medical weeklies replace a former half dozen more special journals. And in these, many of the articles are so technical as to make the reading of only conclusions the part of wisdom.

Efforts to remedy professional inadequacy have proceeded along two lines—improvement of service and more effective application of service. Impelled to self-preservation from the assaults of Christian Science, faith healing, osteopathy, chiropractic (these star witnesses to medical inadequacy), and with, doubtless, in less degree, an altruistic motive, the profession has adopted increasingly higher standards of medical education, preparatory and technical. Medical schools are diminishing in num-

*Read at a meeting of the Nebraska State Medical Society, May 24, 1916.

ber and gaining in quality, as is true of medical graduates. We may safely trust that effort along this line has gained sufficient momentum to carry it over to the standard set by the Committee on Medical Education of the A.M.A.—State medical education—with State schools providing that adequate equipment impossible to privately endowed schools; more largely free from the temptation to sacrifice standards to numbers; with salaried, full time professorships.

Of supplementary health agencies instituted for the more effective application of medical knowledge must be considered first that one having as its object the prevention of disease—the Public Health Service, national and local, including medical school inspection. Instituted in response to the recognition of control as the essential factor in prevention of disease, its effort was first directed toward control of the individual, through compulsory examination, isolation, and enforced treatment, as by vaccination; and later, toward control of environment, through drainage of soil, destruction of parasites, factory inspection, building regulations, etc. To-day we already see the beginnings of effort toward control of heredity.

Established chiefly for the protection of trade interests, and the better-to-do classes, from the ravages of epidemic disease, the Public Health Service has grown increasingly altruistic, and of vastly greater social significance. In so far as it has been adequately supported, and free from partisan political alignment, allowing of freedom of action unrestricted by expedient subservience to individual persons or interests, its workings have been eminently satisfactory. Already it has achieved results of incalculable value. When, with the general institution of non-partisan government, it shall be brought under the operation of civil service, the minor weaknesses which it has exhibited will disappear. To-day, no one desirous of medical progress would advocate its limitation, but rather the extension of its field and the enlargement of its activities. The Public Health Service, supported by taxation, of general application, its staff under governmental control is, in so far as it goes, *State medicine.*

Of supplementary health agencies next come various forms of health insurance, necessitated by the economic inability of at least half the population to avail itself of medical examination and care. All of these, whether they be private (as through lodges, fraternal orders, etc.), supported by dues, and applying only to members; or contractual, between State and private organizations, applying to certain economic classes, State supported, but in part privately administered, as in England; or as proposed in the health insurance measures outlined by the committee of the American Association for Labor legislation, such measures to come before the coming legislatures of New York, New Jersey, and Massachusetts, support is to be divided between workers, employers, and State, and the details of organization and administration left to the medical profession, all of these exhibit certain weaknesses in common—class legislation, friction between privately employed and State employed physicians, increased administrative cost, through multiplication of boards and officials, and lack of specialization, censorship, and control of medical service.

Per capita contract or contract by visit (as operative in lodges, etc.), gives, of necessity, cheap, inefficient, and dishonest service. Unlimited choice of physicians, as in France, has led to inconceivable abuses. Limited choice, as in England, has given rise to similar evils in lesser number. Under all these forms of health insurance the physician is employed as an individual rather than, as would be the case under State medicine, as a salaried member of a specialized staff, working in constant association and cooperation with fellow members, with time rotation in service, his work censored, and his relation to the public impersonal. While the present English panel system, the nearest approach to State medicine, has already accomplished much for profession and public, already leading members of the British profession are calling for its complete socialization.

The recent introduction of health inspection into many large industrial establishments employing thousands of men, the service performed by physicians salaried by employers, has proven the inability of privately-feed medicine to reach a large part of the industrial population until it is more or less incapacitated by disease. Such inspection is instituted primarily in the interests of employers, with the object of increasing efficiency and profits; and often works extreme hardship to the physically defective worker, through loss of employment, or transfer from better to that which is less well paid.

Of plans for bringing the best medical service within reach of persons of moderate means, that of most recent and general interest is proposed by a no less distinguished member of the profession than Dr. Richard Cabot of Boston, in the columns of a popular magazine—that of the voluntary or institutional lay group, in control of hospital facilities, and employing a salaried staff of medical specialists. This plan Dr. Cabot frankly admits to be a buffer against the shock of the coming of State medicine until such time as government shall be by the qualified rather than the unscrupulous. In his distrust of State medicine Doctor Cabot seems to me unfair to the relatively creditable record of governmental administration of public utilities, the postal service, public education, as well as the Public Health Service. Indisputably, in the buying of medical service, as in commercial buying, the group can bargain more advantageously than can the individual, and the larger the group, the more advantageously. However, this group plan will not insure the best medical service. It is not the opinion of one specialist member of the group, but the consensus of specialist opinion that is desirable. To assemble voluntary groups sufficiently large to affect any considerable portion of the community, and possessed of sufficient funds for physicians' salaries and hospital maintenance, with any promise of permanence of membership lay or medical, and with the inevitable prospect of friction between various groups, seems to me to offer insuperable difficulties. The logical outcome of Doctor Cabot's plan is the community group, working through the community group of hospitals—general, contagious diseases, maternity—which is the only group combining permanence, control of adequate funds, authority and representation of the interests of all the people of the community.

Further convincing proof of the inadequacy of privately-feed medicine along all lines is found in the conditions for effective service demanded by specialists in various fields. In general, all emphasize the need of early diagnosis and of continuity of treatment—these being impossible under the present system with its private fee and lack

of control. It is now possible for the patient, whether from financial inability or inertia, to postpone examination by a physician until alarmed by symptoms of disease. And after he has presented himself for examination, and treatment is instituted, he is advised by well-nigh every acquaintance whom he meets, to seek another medical advisor; and if possessed of any income worth while, at every turn he encounters, ready to snatch him, a hungry horde of medical vampires, made vampires by the conditions under which they work.

In a recent symposium on tuberculosis, before an Eastern State medical society, it was the consensus of opinion that adequate handling of the tuberculosis problem called, specifically, for notification and intitutional treatment—dispensaries with visiting nurses for ambulatory cases; sanatoria for incipient bed cases; hospitals for advanced cases; and, in general, for improvement of industrial conditions, eradication of poverty, money and more money, and authority. What system of practice save State medicine can measure up to these requirements?

Dr. William F. Snow, general secretary of the American Social Hygiene Association, who presumably voices advanced opinion as to the prevention, diagnosis, and cure of venereal disease, names as essential conditions for its eradication: notification; provision of public health laboratories for free bacteriological and serological examinations; ample facilities at public expense for clinical diagnosis and advice; free treatment of ambulatory cases, hospital care for advanced cases; the following-up of such cases by social service workers; compulsory examinations generally of large bodies of men, as in schools and industrial establishments, and wherever food is handled. As necessary accessory measures are named: public education; provision of ample public facilities for wholesome recreation; reorganization of industry; elimination of alcoholic drinks. What part, may I ask, has privately-feed medicine in such a program?

As regards cancer, hope of discovery of causation and consequent prevention rests in the research of salaried specialists. Here early diagnosis is above all imperative. Its accepted treatment—surgery—with the surgeon's fee, the cost of hospital care, the expense of subsequent *x*-ray or radium treatment, cannot be obtained, except through charity or at public expense, by many of its victims, and imposes a grievous burden upon the families of all its victims save the very wealthy. Indisputably, dread of the expense of treatment is in part responsible for delay in seekng medical advice. The diagnosis and cure of no other disease more imperatively calls for State medicine.

Recently, Dr. G. E. de Schweinitz, the distinguished ophthalmologist, in a plea for the conservation of vision and prevention of blindness, called attention to the need of effort along legal, institutional, social, and industrial, as well as professional lines. He demanded for the individual case of ophthalmia neonatorum notification and hospital treatment, and called attention to the fact that only two hospitals in Philadelphia admit such cases. For trachoma he demanded quarantine; for glaucoma, education of the public as to symptoms, and correlation of social work in treatment; for myopes, classification and training for appropriate employment. I am sure you will grant this to be a program for State medicine. Already, under the working of medical school inspection, certain municipalities have assumed responsibility for removal of diseased tonsils and adenoids, and the correction of errors of refraction.

Dr. William Palmer Lucas, physician in chief in the department of pediatrics in the University of California, in outlining an ideal child welfare service for the community, calls for cooperation between department of pediatrics, hospital, laboratory, medical school inspection service, and board of health, holding that only through unification of all these agencies can the problems of child welfare be solved. Such unification is possible only under State medicine.

Consider that triad of disease—heart, kidney, and vascular—the menace of our middle age, the Nemesis of our high-geared civilization. Leading authorities name as necessary for their limitation —early diagnosis, medical and social supervision, and appropriate employment. As steps in the prevention of organic heart disease (with application to kidney and vascular disease as well) are demanded: medical school inspection for early detection of defects; a special vocational training for those showing defects; control of infections; public education as to causation and prevention of such defects; compulsory examinations at intervals after leaving school; and I myself would add—the barring from school and college curricula of strenuous and competitive athletics—basketball, football, track athletics.

There has been recently brought to professional attention by a leading member of the New York profession, whose name I do not at this moment of writing recall, the valuable therapeutic asset which this country possesses in its mineral springs, especially those at Saratoga; and the necessity, judging by European experience, of State ownership and control, if they are to be developed and operated in the interests of the public health.

Let me but refer to the inadequacy of privately-feed medicine in the field of orthopedics, with its requirement of minutely specialized knowledge, costly and extensive equipment, and prolonged institutional care; in the treatment of neuroses, where institutional treatment is imperatively demanded, the same free of cost, or at a cost below that possible in a private sanatorium; in the treatment of imaginations of disease, which have filled the Christion Science churches, and the waiting rooms of practitioners of medicine on a bath house basis. Let me instance the absurdity of conceding to the Public Health Service control of acute epidemic disease through quarantine, and then relinquishing its treatment to the general profession. And I might continue indefinitely.

In view of all this, I am not liable to the charge of proposing a Utopia when I affirm the coming of State medicine, nay, that it has all but arrived. If I may venture an opinion as to the manner of its coming it is that it will be through utilization of the appropriate organization already existant—the Public Health Service, through the natural evolution of this service, which at present has been worked only upon the surface, and is capable of vast expansion.

Doubtless the chief obstacle to the coming of State medicine will be the privately-feed medical profession. A change in the professional attitude is demanded. The medical monopoly, forced to choose between economic advantage and the public good, and as between public and profession, assuming the attitude, "my profession, right or wrong,"

must go, and that speedily. Medicine exists for the public, and not the public for medicine. It will be the part of professional wisdom to accept the change from within before such time as it shall be imposed from without.

ALKALOIDAL ADJUVANTS IN GENERAL ANESTHESIA.

By RAYMOND C. COBURN, M.A., M.D.,

NEW YORK.

The oscillation of the pendulum in human affairs is quite well shown in the development of general anesthesia. The first attempts, followed by more or less success, according to authentic writers, to attain loss of sensation for surgical procedure, were by substances derived from the vegetable kingdom. Then came the discovery of the inhalation anesthetics, and the exclusive use, practically, of these agents, for this purpose, for the next half of a century. In our own day the pendulum is swinging back to the vegetable kingdom for either the sole or adjuvant agents in the production of approved anesthesia.

The patient who realizes that an operation is impending is more or less apprehensive of the procedure, discomfort, suffering, and result. This preoperative fear is highly productive of shock, and it is here that the primal "anesthetizing draughts," now displaced by the refined and more certain and quicker acting alkaloidal solutions hypodermatically administered, prove their usefulness. Under the influence of morphine the nerve and cerebral centers are tranquilized, and a neutral psychic state induced, that is, fear is banished. With preliminary morphine, the induction of anesthesia is smoother and more rapid, consequently there is less struggling. All observers agree that patients who have struggled during induction do badly in anesthesia and are very prone to suffer from shock and cardiac weakness. Gatch has shown that this struggling produces excessive cardiac strain. In addition, being a narcotizing agent itself, morphine lessens the amount required of the principal anesthetic.

In the administration of morphine preliminary to the chief anesthetic, either atropine or scopolamine, or both, should be combined with the morphine. When morphine is used without scopolamine the dose should be 1/6 grain to the average adult, and if nitrous oxide is to be the chief anesthetic 1/150 grain of atropine should always be combined with this amount of morphine. In robust males this medication may properly be increased to 1/4 grain morphine and 1/100 grain atropine. If ether is to be the principal anesthetic it is not so essential that atropine be combined with the morphine, although I consider it is always preferable to do so. When scopolamine is used 1/6 grain morphine and 1/200 grain scopolamine is the preferred dose for the average adult, and this medication should be given one hour prior to the time of operation; whereas if morphine and atropine alone are used the time of administration is preferably one-half hour before the operation. When scopolamine is combined with morphine the tranquilizing effect, especially upon the higher brain centers is quite pronounced, and the pulse rate and respiration are both thereby decidedly lessened in frequency.

Combining either atropine or scopolamine, or both, with the preliminary morphine overcomes one of the objections that has been urged against such use of this narcotic, namely, that it interferes with the utilization of the pupil as a guide to the depth of anesthesia. With the use of either of these combinations the size of the pupil is a more reliable guide to the depth of anesthesia than when no preliminary medication is used, for while the pupil does not begin to dilate till a slighter deeper anesthesia is attained, yet when the pupil is dilated it is more surely indicative of a deep anesthesia, as this medication tends to prevent reflex dilatation under light anesthesia. Besides, the upper lid reflex is a much more reliable sign of the depth of anesthesia than is the size of the pupil, or its reaction to light, either with or without preliminary medication.

It is properly held by those who have raised objections to this preliminary alkaloidal medication that it should be employed only by those versed in its use. But, indeed, no anesthetic, or system of anesthetization, is safe enough to be placed in the hands of the unskilled and untrained. This is not the age for a skilled profession to decry anything that is of benefit simply because its use requires training and experience.

There is decidedly less postoperative nausea and vomiting when the preliminary alkaloidal medication is used. This is probably due to the fact that this medication, plus the amount of the principal anesthetic that is then necessary to produce the required depth of anesthesia is less toxic than is the larger amount of the principal anesthetic when used alone to produce the same depth of anesthesia. This disposes of the objection that it is not advisable to introduce into the system several such toxic agents at one time, for in actual practice there is less toxication manifested when there is a proper combination of these synergistic agents than when only a single narcotic is used.

It is not contended that this preliminary medication should be indiscriminately used in all cases, but rather that in all cases in which it is used there should be discrimination. The disintoxicating organs of the young are not as fully developed as are most of the other organs; and in the aged the disintoxicating organs have a subnormal activity, so, in the extremes of life, if used at all, the dose of the preliminary alkaloids must be smaller accordingly than the usual medication for these ages. Patients who are very ill, especially those suffering from the various toxemias and toxications, and who, therefore, require smaller amounts of narcotics to produce a given effect, should be given only small doses of the preliminary alkaloids. Most of the so-called idiosyncrasies against morphine are found in the last mentioned class, more particularly the chronic, and are, therefore, not true idiosyncrasies. In such patients the eliminating and disintoxicating organs are constantly overworked, and consequently cannot adequately respond to the sudden increase in toxic substances thrown upon the system. Such patients do not tolerate ether any better than morphine, as these substances are so toxic to them that they act in the nature of "the last straw."

Of even greater importance than the preliminary time of the operation to prevent centripetal impresmedication is the use of alkaloidal adjuvants at the sions passing from the field of operation. Crile's exhaustive researches show that unless the operative field is blocked off from the central nervous system through local anesthesia, noxious impulses pass continually from the traumatized area to the brain, even though the patient is surgically anesthetized; that the anesthetized patient is not as a cadaver merely because there is no visible response

to traumatism; but that from the traumatized area impulses pass to the brain and produce injury just as certainly (but not to as great a degree) as though the patient were completely conscious; that the brain "feels every thrust of the knife and traction on the viscera, even though the patient be profoundly sleeping." As soon as the profession thoroughly grasps the full significance of these teachings a new spirit will pervade surgery, and the time is not far distant when lack of gentleness will be considered as unscientific as lack of asepsis.

The technique, briefly summarized, is infiltrating the skin and each of the subsequent layers in the line of incision, with a one-fourth per cent. solution of novocain, and in certain cases the deeper layers, but away from the incision with a one-sixth per cent. solution of quinine-urea hydrochloride.

Objection is raised at once that this procedure consumes too much time, but this objection, like most of objections to new methods, is more theoretical than practical. My own experience has been that the surgeons using the nerve-blocking technique consume less time to the average than those not using it. As this seems strange I venture an explanation. Those using this method are strongly imbued with the idea that they must work gently, otherwise there would be no need of using this technique, therefore they do no unnecessary surgery. If the getting-in process is delayed it is only slightly so, and the getting-out procedure is more than correspondingly accelerated, for the no-injury idea is so predominant. "Get-in" and "get-out," with emphasis on the latter, are not bad ideas in abdominal surgery, from the viewpoint at least of the anesthetist.

Nitrous oxide is the general anesthetic *par excellence* to use in conjunction with these alkaloidal adjuvants. The resulting anesthesia is so light that whenever the surgeon passes beyond the blocked area changes in the patient's respiration immediately warn him of his transgression, so that he may either cease his traumatizing, or extend his local anesthesia. This system of anesthetization enforces gentleness. When the technique is perfect there is rarely need of any adjuvant ether whatever. Even in such procedure as the removal of the gall-bladder, which otherwise requires the deepest type of general anesthesia, I have been able to dispense with ether entirely; the operation is practically shockless, the patient's vitality is conserved, his resistance is left unimpaired, and his ultimate recovery is thereby rendered more certain.

Bretton Hall, Eighty-sixth Street and Broadway.

Medicolegal Notes.

Administration of Narcotics to Relieve Pain and Cure Drug Habit.—In a prosecution under the Texas statute making it unlawful to prescribe a narcotic drug for an habitual user thereof, it appeared that the person to whom morphine was administered had been a morphine fiend, and had become emaciated and was confined to her bed. The defendant, as physician, administered the morphine for two purposes: First, to relieve her of her present suffering; and, second, to cure her of the habit. The evidence of the woman showed that he succeeded in both. The Texas Court of Criminal Appeals held that the statute does not prohibit the prescribing of the drug when necessary to alleviate pain or cure the drug habit. It was held to be error to exclude the defendant's evidence that he gradually reduced the size of the dose, and finally ceased it altogether; that being material to show that the drug was prescribed in an effort to cure the habit. It was also error, there being evidence that the drug was prescribed to alleviate pain, to refuse to charge that if the drug was administered in an effort to relieve pain the defendant physician was not guilty.—Fyke v. State (Tex.) 184 S. W. 197.

Basis for Hypothetical Question.—In an action for personal injuries error was claimed in not sustaining an objection to hypothetical questions asked a medical witness, Dr. Platt. This witness had heard all the testimony in the case, including the testimony of plaintiff, and of his attending physician, Dr. Comstock, as to his condition. He was asked his opinion as to the permanency of the injuries to plaintiff's jaw, basing it upon the testimony of plaintiff as to his condition, and the testimony of his attending physician as to what he found and what he did, excluding any opinion he had expressed. The objection was that the question "does not give the elements, and is too broad as it does not give in detail the facts, but leaves to the witness to eliminate that which his own judgment may induce him to eliminate." Other questions of like tenor were asked, objected to on the same ground, and permitted to be answered. The answer of the witness was that in his opinion the injury was permanent.

The appeal court did not think that the questions were fairly open to the objections made. It is of course true that it must be made plain to the jury as well as to the expert what facts he bases his opinion on, and he must not be left to decide between conflicting facts, but must assume as true the facts stated in the question or those found in the testimony he is asked to base his opinion upon. But this witness had heard plaintiff testify, not only as to the condition of his jaw, but as to the history of the case, and the history and habits of the plaintiff. He was asked to give an opinion based upon this testimony, and the testimony of the attending physician as to what he found. It appeared from the cross-examination of the witness that the past history of the patient and his habits were elements necessary to be considered in giving an opinion as to the permanency of the condition of his jaw, and the witness understood that these elements were included in the hypothetical questions asked. The claim was that these elements were not included in the questions and not shown by the testimony, and therefore that the expert must have based his opinion in part on knowledge acquired outside of the court room and not disclosed to the jury. If this had been the case, the testimony should have been stricken out, but the record did not bear out the claim as to the facts. The past history of the patient, as well as his past life and habits, was quite fully disclosed by his own testimony and the testimony of Dr. Comstock, and the expert was asked to assume this testimony to be true and to take it into consideration in giving his answer. The court did not think that the expert "usurped the functions of the jury," or that there was any error in the rulings made in regard to his testimony. Nor was there anything in the claim that the testimony of the doctor showed that he was not competent to testify.—Johnson v. Quinn, Minnesota Supreme Court, 153 N. W. 267.

Hypothetical Questions.—The general rule is that a hypothetical question should include a full statement of all material facts, if they are uncontradicted, or such facts as the interrogating party may reasonably deem established by the testimony of his witnesses, but should not assume facts not warranted by the evidence. If opposing counsel is of opinion that material facts are not included in a hypothetical question he may incorporate these facts in questions asked on cross-examination, and may also frame questions involving a consideration of facts which he contends are established by his evidence. The exact form of the question and the extent of the examination are under the control of the trial judge, whose duty it is to see that the examination is properly conducted.—Albert vs. Philadelphia Rapid Transit Co. (Pa.), 97 Atl. 680.

Medical Evidence as to Damages.—In an action for personal injuries where there was evidence that prior to the accident the plaintiff had enjoyed good health, that immediately thereafter she was removed to a hospital in an unconscious condition and was confined to bed six or eight weeks and was absent from her employment for some months, and frequently since the time of the accident was subject to convulsions, it was held that the testimony of physicians, who made their examination more than two years after the accident, as to her condition is not to be stricken out on the ground that the connection between the accident and the plaintiff's present condition was not shown.—Albert vs. Philadelphia Rapid Transit Co., Pennsylvania Supreme Court, 97 Atl. 680.

THE MORBIDITY OF DRUG INTOXICATIONS.

THE success in the present reduction of disease, and the increase of the span of life from an average of nearly 12 years in the Dark Ages to the present average of 50 years, through achievements in preventive medicine, have been mainly the result of a reduction in the infectious disease incidence. In a great measure, this is due to the fact that the attack on the infectious disease element is an extrinsic one which places but a slight burden of moderation on the individual, the measures necessary in this sort of preventive work even helping to increase the personal and the esthetic conveniences of every one. But because there is required an intrinsic endeavor to render it effective, preventive medicine has had little appreciable effect upon the incidence of the degenerative diseases which appear in persons in the prime of life—between 40 and 60 years of age. It is estimated that the annual death rate from the degenerative diseases, exemplified in kidney, heart, and blood-vessel diseases has increased over 100 per cent within the last 20 years. These figures bear mute testimony to the increasing desire of the sedentary for artificial stimulation and of the overstrenuous for artificial sedation.

The resistance of the body is reduced by such things as alcohol, tobacco, narcotics, occupational poisons, and syphilis. While alcohol leads the list of drug intoxicants in being the most prolific cause of the degenerative conditions, both of the body and of the central nervous system, it rarely operates alone, being usually accompanied by dissipation of other kinds, and the "strenuous life" and syphilis often add their effects.

Moreover, quite apart from the increased use of strong alcoholic beverages, there has been an enormous increase in the manufacture and consumption of patent medicines. The public is persistently dosing itself with drugs of various kinds and of various actions. Some are stimulants, some sedatives, and some combinations of both, and the taking of them is often a fad or a pure habit, the consumers not knowing really why they take these medicines. To be sure, many of these patent medicines are purely alcoholic, and the effect is that of alcohol. With all of them the body is put to the trouble of eliminating highly irritating substances which have the tendency to reduce the vitality of the eliminating organs, as well as often positively injuring them. It is through such injury that the general fibroid changes are often set in motion.

The expenditure for these unproductive and highly injurious products has been estimated to be over $150,000,000 a year. The increase in the population of this country has been nowhere in proportion to the increase in the consumption of drugs. While the population has increased about 100 per cent in the last twenty years, the increase in the use of these products has been over 750 per cent.[1] All drugs, no matter what their proper value is, are potentially harmful. They are not intended for consumption at random, but only under expert guidance. All the untoward and poisonous effects of these drugs are met with in the consumers. There are the effects on the heart, blood-vessels, kidneys, muscles, nervous system, etc. Because the body often establishes a tolerance to these poisons, an increasing amount must be used to get the original effect, and so the habit is formed.

What the remedy for this great evil may be is a secret still in the laps of the gods. Prohibition notoriously does not prohibit, except to a limited degree, and the various antinarcotic laws, including the defective and vexatious Harrison law, merely make it more difficult and more costly for drug victims to get their favorite narcotic or stimulant. As for patent medicines, the enforced publication of their formulæ and their percentage of alcohol has little or no deterrent effect. Nevertheless, the curbing of the alcohol and drug-intoxication habit is one of the most important considerations in the problem of increasing the stamina of the people, of reducing the death rate, and of increasing the span of life. Perhaps the research foundation recently established in Hartford may succeed in throwing some light on this dark subject.

PHYSIOLOGY AND PSYCHOLOGY, AND THEIR EUPHORISTIC HARMONY.

PROGRESS in knowledge depends upon pressing forward toward an unachieved goal. Attainment of the end would defeat advance in its very initial impulse. Therefore the elusiveness of the goal toward which psychology turns and its refusal to yield clear knowledge of the intimate relation of mind and body afford emphatic proof of the importance of the effort directed thither. What is demanded, what must be accomplished in the search is this. Our pragmatic knowledge must be increased and our power of control enlarged. We must continually widen the horizon and shift our viewpoint toward an ever better adjustment of mind and body so that the former has a more complete and harmonious mechanism at its disposal and so that the latter is not turned aside to the service of mental caprice and unbalance. Every sincere effort, then, from either side of the problem, to throw light upon this obscurity is just so much practical service rendered to the theory and the practice of life in its possibilities.

George Van Ness Dearborn, in an article on

[1] Martin I. Wilbert, Reprint No. 227, Public Health Reports.

"Movement, Cenesthesia, and the Mind" (*Psychological Review* for May, 1916), throws a hearty "euphoristic" interest into the problem in his study of the flood of "animus" which pours into the cortical "gray" from the environment which our own physical bodies afford in themselves or as transmitters of external stimuli. Earlier studies of his, particularly "Certain Further Factors in the Physiology of Euphoria" (*Psychological Review*, May, 1914), discuss more fully certain divisions of physiological activity which furnish a constant and important stream of influences which must affect psychological well-being. These are chiefly the nutritional area so greatly extended by the presence and function of the intestinal villi for absorbing and storing the lipoid and perhaps protein substances conducive to the euphoria of the nervous system, also the great cinesthetic system of sensations, and by no means of least importance the epicritic sensibility of the skin area. The later study bases itself upon these and other organic contributing factors, but concerns itself chiefly with the universal movement continually present in the body in which all parts of the organism have their part and likewise with "cenesthesia" or the sum of influence which the afferent nerves continually transmit to the gray matter.

All of this is of an importance not to be set aside. It must be and is the basis of accurate laboratory research in order to determine with increasing accuracy and knowledge how the organic processes can influence our psychic euphoria, and therefore our capacity, and to know what the definite relationships are which make psychology and physiology mutually dependent. Yet just here the author is hampered still by the psychophysical attitude of which he himself complains. The reason is not far to seek. The relations of mind and body are reversed. There is too much about "behavior's nuerility," "skeleton of mind," and the like, from the point of view that makes the mind the product of this cenethesia of all the vast contributing area of bodily tissues comprised in our organic make-up. The reactionary influence of a complex organism upon the mind that controls and utilizes it is quite another thing from the "raising a good quality of mind" from such influences. Headed in the right direction, phylogenetically, from the mind to its potentially perfected implement, the body, then it is possible to enter into the depths of practical discovery. Then the unconscious or "subconscious" is freer for investigation even through the study of this organic cenesthesia and movement. The autonomic thus becomes but a division of the vaster unconscious, but perhaps the relation is even closer than that the author conceives between the higher nervous action and the autonomic "subconscious" of the nervous system on the one hand, and the conscious and unconscious mind on the other, the master, director, and artisan, too, of the organism. Ideational euphoria, he believes, lies beyond physiological euphoria, but that it arises from cortical associations reflects again the reversed point of view. Mental readjustments effected through purely mental therapy, which takes into account the individual psychical determinants, the sum of which may well form a psychic cenesthesia, prove themselves so effectual in dissolving physical dysphoria that we must conclude that the author has laid the emphasis on the wrong side. There is such rich suggestion, however, in Dearborn's discussions of the contributing physiological factors in the close relationship of what psychoanalysts have styled "libido areas" and psychic states that his work is stimulating to follow. He has pushed onward into the unknown and cast out some very definite charting lines for steady scientific advance.

THE DETOXICATING ACTION OF SLEEP.

While this title may at first suggest something new in physiology, it only connotes the old view that sleep is due very largely to the accumulation of waste products and persists until these have been taken up by the circulation. It is a corollary, therefore, that in loss of sleep the body becomes in a measure intoxicated. In animals deprived of sleep death occurs at the end of three or four days with a gradual lowering of temperature and reduction of erythrocytes to 2,000,000. Under the combination of excessive muscular labor and injection of meat extractives an animal succumbs in from thirty to forty hours. The injections made at the conclusion of the labor precipitate a condition of extreme lassitude. According to certain authorities sleep is not even a function *per se* but the result of fatigue toxins. Upon the view that the thyroid gland presides over disintoxication the claim is made that in hypothyroidism there is always a tendency to drowsiness. From a similar viewpoint the power of alcohol to produce drowsiness and deep sleep has been ascribed to an overstimulation of the thyroid; for while alcohol in small doses increases the activity of the gland the reverse becomes true when large quantities are taken.

The toxic or antitoxic nature of sleep is thus discussed in a brief article by De Castro in the *Revista de Medicina y Cirugia de la Habana* for July 25. It is indeed evident that some of the older views of sleep have not made good. We do not know whether or not sleep is dependent on a particular state of the cerebral circulation, for it apparently occurs with anemia, hyperemia, or the ordinary status. Drowsiness after a full meal is still held to be due to a derivation of blood from the brain and it has been shown that when one drops asleep there is a sudden lowering of blood pressure. But no theory of sleep can be devised on this basis which can begin to account for all its phenomena. A good night's rest from which a subject awakes refreshed and active, appears to show that all fatigue toxins have been expelled from the cells. But it is evident that such a slumber can have little in common with the somnolence which follows a gluttonous meal during which toxins accumulate and from which the subject wakes unrefreshed and with most wretched subjective sensations. Any sleep apparently normal which fails to refresh could not have been true slumber of the detoxicating type.

The neurasthenic, regarded usually as poisoned by his cell products, may be a sound sleeper in appearance but has no corresponding advantage over

a neurasthenic with insomnia, and at no time of day does he feel so devitalized as upon waking. Conversely the active man who can do with little sleep must have superior facilities for detoxication, or perhaps for some unknown reason he is more immune than others to fatigue poisoning. The fact, however, that many individuals who lead sedentary lives are able to obtain prolonged and refreshing sleep seems to show that sleep cannot be regarded merely as a measure of fatigue poisoning. To account for such cases we have to invoke the agency of habit and the adaptability of mankind to methods of living.

REVACCINATION AGAINST TYPHOID AND PARATYPHOID FEVERS.

PARATYPHOID fever is said to be extremely frequent in the various armies in Europe. There has been no severe epidemic of typhoid since the commencement of the war, but from almost the very outset of hostilities, there has been a somewhat wide prevalence of paratyphoid fever. In the *Medical Press*, August 2, 1916, F. Widal and I. Gourmont point cut that on account of the extensive prevalence of this disease Landouzy, as far back as December, 1914, indicated the practice of vaccination as the sole effective prophylactic procedure that could be adopted to fight successfully against this malady and called for a comparative study of the method of successive vaccination against typhoid and paratoyphoid fever respectively, and of that of double vaccination carried out by the injection of a mixture of the typhoid and antityphoid bacilli.

In August of last year such tests were made by one of the writers, who concluded that the final choice should be that of a triple vaccine, consisting of a number of typhoid bacilli equal to that contained in the simple antityphoid injection, and a double number of each of the paratyphoid bacilli, A and B. This observer has reported experiments of which the results furnished cogent proof of the powerfully immunizing action of such vaccines when heated; and he has also shown that this vaccine had the effect of making the several specific antibodies of each of those microbes appear in the blood of the vaccinated individual and has demonstrated the harmlessness of his procedure. Widal and Gourmont state that they have revaccinated with the triple vaccine about 4,000 persons who had previously been immunized with the simple antityphoid vaccine. Furthermore, they always used the triple vaccine even in the persons who had had typhoid, for the reason that they believed that even in such cases it could not be other than advantageous to profit by the supplementary antityphoid vaccination for the purpose of reinforcing the degree of immunity against the typhoid infection itself. In summarizing their results they assert that the triple vaccine suffices for all the requirements of both antiparatyphoid and antityphoid revaccination.

As paratyphoid prevails to a considerable extent among our troops on the Mexican border, it might not be amiss to test the value of the triple vaccine there.

THE POLIOMYELITIS PANIC.

A MEETING of the town board of Oyster Bay, L. I., held on Monday of last week, was taken possession of by a number of indignant citizens who passed a resolution regarding the poliomyelitis situation, setting forth "That it is the sense of this committee that the credulity of the public has been preyed upon sufficiently long in the neighborhood; that the business interests are sufficiently paralyzed; that frenzy and terror have been sufficiently propagated; that it is high time for a return to common sense, the discharge of the medical maniacs, the resumption of local business, the recall and restoring to confidence of our easily scared summer residents, and the application of common horse sense to the so-called epidemic with which we as well as other communities have been afflicted." This is a little strong in spots, but it is only what was to be expected as a natural reaction against the quarantine hysteria that is raging epidemically in this neighborhood. When a town stations men at every point at which a ferocious child may possibly enter, even though it wants only to pass through, and drives back the invader practically at pistol point unless it is armed with a certificate from a board of health—and in certain places even then, that community has plainly lost its head. When, furthermore, the healthy child, admitted on the strength of the official certificate, is immediately quarantined and forbidden to leave its home for twenty days, the community so ordaining is devoid of reason. Although poliomyelitis has not been proved to be spread by direct contagion, and possibily never will be, it nevertheless is for the present a justifiable precaution to isolate the sick; but to war upon the well, to forbid children in evident health, riding in an automobile, to pass through the town at a speed of ten or more miles an hour, and even to expell children known to be in perfect health from a town in which they have been passing the entire summer because in the winter they live in New York City, betrays a degree of hysterical panic and craven fear that, were it not a fact, would be beyond belief. A Sicilian peasant mob in time of cholera could hardly do worse, but theirs would be the sin of the mindless while the suburban health officer is supposed to know better.

News of the Week.

Poliomyelitis Receding Rapidly.—The last days of August witnessed a sharp decline in the number of cases of poliomyelitis in New York City, and for the week ending September 2, 477 cases only were reported. The total number of cases to September 6, was 8,330, of which 2,047 were fatal. The passing of the epidemic was clearly indicated by the fact that the Willard Parker Hospital, which had at one time nearly 1,100 patients suffering from the disease, on September 4 harbored only 950. On the same date there were in all the hospitals in the city 3,784 patients under treatment. Dr. Charles E. Banks of the United States Public Health Service, in charge of the quarantine regulations in reference to infantile paralysis in New York, has protested against what he calls the inconsistent quarantine policy inaugurated by local health authorities in towns near New York City, especially in Westchester and Nassau Counties. He has suggested that there should be some State board which could regulate the action taken by

local authorities in small villages, so that a uniform and sensible method of guarding against the spread of disease could be promoted without interference with the business of a community. It really is time that some official notice should be taken of the inane action of many so-called health officials. September 25 has been definitely decided upon as the date for the reopening of the public schools in New York City, provided, of course, that no flare-up of the epidemic occurs before that time.

The after-care of children discharged from the hospitals as cured has been considered by the Department of Health, and it has been arranged that in each case a formal notice of the approaching discharge of a child shall be sent to the parents, setting forth the child's condition, and urging that the family physician be consulted or that the nearest orthopedic dispensary (a list of these dispensaries being inclosed) be visited. The facts in each case are sent also to the director of the committee on after-care, Dr. Donald E. Baxter. In this way, it is hoped, many permanent disabilities may be avoided. The Department of Charities of the city has estimated that $100,000 will be needed for the care of those convalescent from poliomyelitis up to January 1 and more after that date. The Department of Health has already received over $26,000 in voluntary subscriptions for the purchase of braces and other appliances.

Changes in Red Cross.—The active executive management of the American Red Cross at National Headquarters in Washington, passed on September 1 to Mr. Eliot Wadsworth of Boston, who has been elected to succeed Major General Arthur Murray, U. S. A., resigned. Gen. Murray has devoted himself to the constructive upbuilding of the Red Cross for the better part of a year. Mr. Wadsworth has already had considerable experience in war relief matters, having served as a member of the Rockefeller Foundation War Relief Commission in 1915, as a member of the Poland Relief Commission, and later as director general of the International Commission for the Relief of Poland.

Dental Hygiene at Columbia.—The New York School of Dental Hygiene has become allied with the new Columbia University School of Dentistry and the College of Physicians and Surgeons. The school will open on September 27, classes being held in the Vanderbilt Clinic.

Street Accidents.—The National Highways Protective Society reports that during the month of August 48 persons, of whom 25 were children, were killed on the streets of New York by vehicles. In the State outside of New York City during the same time 54 persons were killed by automobiles, trolleys, and wagons while in New Jersey 26 persons were killed in the same way. In New York State 8 persons were killed at railroad grade crossings, as compared with 17 during the same month of last year.

Inquiry Into Garbage Disposal.—Dr. Linsly R. Williams, Deputy Commissioner of the State Department of Health, has been appointed by Gov. Whitman to conduct an investigation into the proposed building of a garbage disposal plant for New York City on Staten Island. The taking of testimony was begun at Borough Hall, St. George, Staten Island, on August 28, and some thirty experts will be examined. The building of the plant has been bitterly opposed by some of the residents of Richmond Borough.

Tuberculosis Test Town.—The National Association for the Study and Prevention of Tuberculosis is sending representatives through New York and Massachusetts in search of a town of about 100,000 population, in which studies may be made of the new theories for the control and elimination of tuberculosis. The officers of the association desire to find for the test a town which has some industries, since tuberculosis is a poor man's disease, one not too far removed from industrial centers, and one with but few commuters. It is planned to expend about $150,000 in the experiment.

Paratyphoid in Camp.—An outbreak of paratyphoid is reported in the camps of the New York division of the National Guard in Texas.

Study of Infant Mortality.—The seventh annual meeting of the American Association for Study and Prevention of Infant Mortality will be held in Milwaukee on October 19 to 21, 1916. The preliminary program includes a discussion of measles and pertussis, a symposium on governmental activities and vital and social statistics in regard to infant welfare, and discussion of public school education for the prevention of infant mortality and of nursing and social work in rural communities. Full particulars may be obtained from the executive secretary of the association, 1211 Cathedral Street, Baltimore, Md.

German Hospital Red Cross Unit.—The complete equipment of an American Red Cross base hospital unit with a staff from the German Hospital, New York, has been made possible by a gift of $25,000 from Mr. Fritz Achelis of this city. The unit is now being organized by the Military Relief Department of the Red Cross. Dr. Frederick Kammerer, who recently returned from active service with the German Army, has been made director.

Civil Service Examination.—The United States Civil Service Commission announces an open competitive examination for both men and women, for the purpose of filling a vacancy in the position of medical interne in St. Elizabeth's Hospital, formerly the Government Hospital for the Insane, Washington, D. C. The position carries a salary of $900 a year and maintenance. The examination is open to graduates of reputable medical colleges or students in their senior year. Candidates must be unmarried, and twenty years or over on the date of examination, and must not have graduated previous to the year 1914 unless they have been continuously engaged in hospital, laboratory, or research work along the lines of neurology or psychiatry since graduation. Application blanks may be obtained from the United States Civil Service Commission, Washington, D. C.

Removals.—Dr. Frederic E. Sondern announces his removal to 20 West 55th Street.

Dr. Charlton Wallace has removed to 11 East 48th Street.

Obituary Notes.—Dr. Warren Fisher Gay of Boston, Mass., a graduate of the Medical School of Harvard University in 1893, and a member of the American Medical Association, the Massachusetts Medical Society, and the Suffolk District Medical Society, died suddenly at his home, on August 26, aged 50 years.

Dr. William H. B. Pratt of Brooklyn, a graduate of the College of Physicians and Surgeons, New York, in 1867, consulting physician and a member of the Board of Managers of the Methodist Episcopal Hospital, Brooklyn, consulting physician at the Home for Dependent Children and the Home for

Aged Men, and a member of the American Medical Association, the Medical Society of the State of New York, and the Kings County Medical Society, died at his home, on August 27, aged 74 years.

Dr. Ernest Watson Cushing of Boston, emeritus professor of abdominal surgery and gynecology at Tufts College Medical School, Boston, a graduate of the College of Physicians and Surgeons, New York, in 1871, and a member of the American Medical Association, the Massachussetts Medical Society, the Suffolk County Medical Society, the American Gynecological Society, and the American College of Surgeons, died at the Cushing Hospital, of which he was the head, on August 27, aged 69 years.

Dr. Howard Fellows Morse, formerly of Lynn, Mass., a graduate of the University of Vermont, College of Medicine, Burlington, in 1904, died suddenly, at his home in Center Harbor, N. H., on August 15.

Dr. George Whitehouse Ryan of Boston, a graduate of the Tufts College Medical School, Boston, in 1899, died at the Commonwealth Hospital, after a short illness, on August 15, aged 44 years.

Dr. Hugh L. McLaurin of Dallas, Tex., a graduate of the Medical Department of the Tulane University of Louisiana, New Orleans, in 1884, and a member of the American Medical Association, the State Medical Association of Texas, and the Dallas County Medical Society, died at his home suddenly, on August 11, aged 54 years.

Dr. Edward E. Flagg of Moreland, Okla., a member of the American Medical Association, the Oklahoma State Medical Association, and the Woodward County Medical Society, was instantly killed in an automobile accident, on August 18, aged 42 years.

Dr. Augustus Assenheimer of New York, a graduate of the New York University Medical College in 1868, and a member of the New York Academy of Medicine and the New York State and County Medical Societies, died at his summer home in Far Rockaway, N. Y., on August 24, aged 67 years.

Dr. John Wesley Ward of Pennington, N. J., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1866, and for many years medical director of the New Jersey State Hospital at Trenton, died at his home on August 25, aged 76 years.

Dr. John A. Fritchey of Harrisburg, Pa., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia in 1879, and three times mayor of Harrisburg, died at the Presbyterian Hospital, Philadelphia, after a long illness, on August 25, aged 58 years.

Dr. William F. Waldron of Brooklyn, N. Y., a graduate of the New York University Medical College in 1893, died at his home on August 24, aged 44 years.

Dr. Edgar T. Spratling of Atlana, Ga., a graduate of the College of Physicians and Surgeons, Baltimroe, in 1891, a member of the Medical Association of Georgia and the Fulton County Medical Society, and a captain in the Fifth Regiment of the National Guard of Georgia, died suddenly on August 25.

Dr. John Bart Webster of Philadelphia, a graduate of the Medico-Chirurgical College, Philadelphia, in 1887, and a member of the New York State Medical Society, the Medical Society of the State of Pennsylvania, the Philadelphia County Medical Society, and the American Medical Association, died at his home, from heat exhaustion, on August 9.

Obituary.

WILBUR B. MARPLE, M.D.

Dr. Wilbur Boileau Marple of New York, surgeon to the New York Eye and Ear Infirmary, died suddenly, of apoplexy, while playing golf at his summer home, Kennebunkport, Me., on August 30, aged 60 years. Dr. Marple was graduated from Amherst College in 1877, and from the Starling Medical College, Columbus, Ohio, in 1881, since which time he had practised in this city. In addition to his work at the New York Eye and Ear Infirmary with which he had been connected for many years, he served as consulting surgeon in ophthalmology to the Workhouse and Babies' Hospital. He was also a member of the American Medical Association, the New York State and County Medical Societies, the American College of Surgeons, the American Academy of Ophthalmology and Oto-Laryngology, the American Ophthalmological Society, the New York Ophthalmological Society, the New York Academy of Medicine, the American Therapeutic Association, the New York Clinical Society, and the Hospital Graduates' Club.

Correspondence.

DOCTORS, PREPAREDNESS AND THE RED CROSS.

Sir Frederick Treves is one of the most distinguished of British surgeons, and has had a large experience of military service in the Boer war and the present great conflict. He has recently written an interesting article in the *London Times*, in which he states clearly the logical and proper relation between the Sanitary Service of the army and the Red Cross. He says:

"However efficient an army medical service may be, the help of the Red Cross organization is—and ever will be—a necessity. All those who are familiar with the operations of the Army Medical Department in the present war will admit that its work has been beyond praise, and will own, indeed, that it could scarcely be surpassed.

"No army medical service can be maintained in time of peace upon a war footing. There is evolved in such times an elaborate scheme for expansion in war; but one prominent and inevitable feature of that scheme is the enrollment of a vast body of personnel from the civil population in the form of doctors, nurses, orderlies, motor drivers, clerks, cooks, dispensers and the like. In such work a civilian society can act with greater ease and promptness than can a huge organization like the War Office, and thus it is that in the supply of personnel the Red Cross societies have undoubtedly rendered sterling service. In the furnishing of medical and surgical comforts also the Red Cross societies are untrammelled by those very necessary forms and procedures which must be observed by a government body dealing with public funds.

"In the matter of personnel, the Red Cross Societies provide a vent for that ardent sympathy which the people of this country feel for the wounded soldier, and, at the same time, make the bounteous eagerness to be of service which has been so glorious a feature in this unexampled campaign. In this eagerness to be kind, to do something for the wounded and the sick, the men and women of Britain, and of Britain beyond the seas, will not be de-

nied. They insist upon taking their share in the work of mercy; they demand the right to assist; they decline to sit still with listless hands. This resolve of the generous folk of the Empire is the foundation of all Red Cross work, and it has expressed itself in a way of which the country of Florence Nightingale may well be proud."

The same opinion has been reached by the military and Red Cross authorities in the United States. Congress enacted and the President proclaimed some years ago that the American Red Cross was the one agent which should render aid to its land and naval forces in time of war, and that the personnel engaged in this work should constitute a part of the sanitary forces. Even the sphere of activity of this volunteer aid was specified by the President. The service at the front was forbidden to it, being the special and appropriate domain of the medical service of the military establishment. This pronouncement of rude and practical common sense should have power to dispel the romantic dream-picture in which the beautiful young Red Cross nurse (not registered) is seated on the battlefield with the head of the stricken warrior on her lap.

The allotted sphere of volunteer assistance is specified to be at the base of military operations, along the line of communications, on hospital ships, and at hospitals in the home country.

As the military base may be in a foreign country, and if not will be always, we hope, on our borders, the Red Cross in its enrollments of personnel classifies them as follows, according to the locality at which their services will be available:

Class A. Willing to serve anywhere, at home or abroad.

Class B. Willing to serve anywhere within the limits of the home country.

Class C. Willing to serve at place of residence only.

Although the War Department as long ago as in 1912 had prescribed in orders the units which the Red Cross should organize and their sphere of action, and had provided for the registration of these units in the Surgeon General's Office, nothing further was done at that time. This inactivity was due in part to the fact that our people were not at that time interested in questions of preparedness, and in part to the fact that the Red Cross was organized and administered along exclusively civilian lines and without reference to its charter obligations to assist the military forces in war and "constitute a part of the sanitary service thereof."

But when the world-conflict aroused us from our dream of a peace that would be perpetual because we so willed it, the Red Cross awoke also to its responsibilities, and reorganized its administrative machinery so as to meet them. All of its external activities were divided into two great departments of Civilian Relief and Military Relief, each under a director general. At the same time, ex-President Taft was selected to be the administrative head of the society. He presides over an Executive Committee of unusual distinction and virility. Its membership includes the Secretary of the Interior, the Surgeons General of the Army and Navy, and three other men and one woman of national reputation. A colonel of the medical corps, U. S. Army, was selected to be at the head of the new Department of Military Relief. Congress recognized the far-reaching importance of this reorganization by authorizing in the National Defense Act the detail of five regular medical officers for duty with this department. Its director at once placed his department at the disposition of the Surgeons General of the Army and Navy, and proceeded to carry out their wishes and instructions as to the direction and scope of its activities. The Navy to be efficient has to be always on a war footing, and the battle fleet is but little capable of expansion by volunteer units. Its needs in the way of volunteer medical assistance in war will therefore he small and easily met. With the Army, however, the case is far different.

The Army is like a spear of which the regular establishment is the small iron head, sharpened and ready for use, while behind it is the great militia, which is the shaft which must be shaped and fitted to the head when war comes. No nation maintains a sanitary establishment any larger than is actually necessary to care for the regular army in time of peace, and no provision of additional officers is made to meet the needs of expansion. In our Army even this modest requirement has not heretofore been met, and the medical establishment has had to call in additional aid to do its work, even in time of peace, although for the line of the Army a decided surplus of officers has been maintained. Now this medical spear head of trained officers is nearly all required for the service of the front, where special military training is necessary, and only enough will be left for the second zone, the line of communications and base, and the third zone, the home country, to fill the more important administrative positions. The strictly professional work of these zones must be done by the medical volunteers from civil life, and fortunately for the professional workers in these two zones preliminary military training is not essential as it is in the zone of the front.

The supreme importance of the base hospitals is appreciated when it is remembered that in the scheme for the rescue and care of the wounded the base hospital is the first real hospital that the wounded man encounters in his journey to the rear. The so-called field hospitals and evacuation hospitals of the zone of the front are in fact not hospitals at all, but mere shelters for the wounded, where they are put under cover and fed and their wounds are dressed while they are waiting to be transported to the base. They have no trained nurses or comfortable beds with mattresses and sheets, or any real comforts. Not until he arrives at the base hospital does the soldier find a bed where broken bones can lie in comfort, or the grateful ministrations of a Red Cross nurse, or the quiet and order of a fixed hospital. Here also the wounded, except a few emergency cases, will find the surgical staff on whose skill will depend their lives or future usefulness in life. Thus it is clear why the base hospital looms largest among the Red Cross organizations, and why the organization of these was the first task given by General Gorgas to the Director General of Military Relief.

It is evident that here is the crucial point in the care of the wounded, and their interest can be best served by transporting here *en bloc* the trained and skillful staffs of our best hospitals. This is what the Red Cross has now undertaken to do for the medical service of the Army, and twenty-five of these base hospital units are now organized or in process of organization in the best hospitals of our country. It should be clearly understood that though organized by the Red Cross they will not be administered by it. As soon as they are called into service by the War Department or the Navy

Department, they "will constitute a part of the sanitary service thereof," in the language of the President's proclamation, and come absolutely and entirely under military authority, and they will be transported by the military authority from their mother hospital to the military base. The nurses will still wear, as a sort of vestigial organ, the red cross on their caps, but the medical staff will wear the uniform of the Officers' Reserve Corps, U. S. A., the commission of which they will have had from the time of their muster-in as a Red Cross unit.

Another Red Cross unit of great practical value is the field column, which is in fact a sick transfer company, which will bring the sick and wounded from the evacuation hospitals in the zone of the front back to the base hospitals. The field column will use for this transportation motor ambulances or hospital trains or boats, or all three.

In the zone of the home country are yet other units, called general hospitals, which will be organized in the larger civil hospitals or at army posts for the reception of the overflow and the convalescents from the base hospitals. The plans for the expansion of these will be prepared, and the personnel enrolled as far as practicable in advance of the time when they will be needed. There are still other Military Relief activities of the Red Cross, which space does not permit to be described.

The Red Cross, in addition to the organization of units, has undertaken in conjunction with five great national medical societies an enrollment of the profession, so as to acquire a record of the capabilities and special accomplishments of the medical profession of the United States. By an arrangement with the National Association of Nurses, it has enrolled and holds ready for service over 7000 nurses, the cream of the nursing profession of this country. Non-professional personnel is also being enrolled for service in war, such as stenographers, clerks, chauffeurs, cooks and hospital attendants.

The Red Cross Chapter in any city is the local organization, whose duty it is to finance the military relief activities of the community, supervise the enrollment of the non-professional personnel, and give such other assistance as may be needed. As the Red Cross is the accepted agency for medical preparedness, it is clearly the first step of every medical man to "join now," and promote in every way the growth and success of this great national institution.

JEFFERSON R. KEAN,
Colonel, Medical Corps, U. S. A., Director General of Military Relief, American Red Cross.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

TREATMENT OF CONVALESCENT SOLDIERS BY PHYSICAL MEANS — EARLY DIAGNOSIS — SYPHILIS — DIATHERMY—HIGH-FREQUENCY CURRENTS—WHIRLPOOL AND OTHER BATHS—HOT SAND—ACTIVE CONGESTION.

LONDON, August 11, 1916.

MAJOR TATE MCKENZIE, R. A. M. C., has brought before the Surgical Section of the Royal Society of Medicine the treatment of convalescent soldiers by physical means; he compared a great military hospital to a general post office, in which the sick and wounded were sorted into first, second, and third class matter—the first being rapily distributed to Red Cross and other military hospitals, where treatment, operative or general, soon enabled them to return to the line. The second class had further to stay at a convalescent institution commanded by an officer of the R. A. M. C., where they could obtain treatment by physical means, including regulated exercise; many of this class found their way back to the front. The third class presented more difficulty, as they were so chronic as to be referred from depot to depot. For some months now such cases have been sent to special depots, each under a competent officer for purposes of discipline but with a medical officer attached. It is hoped that men fit for light duties may be able to release stronger officers for active service and may also allow the discharge of men from whom no further satisfactory work can be expected. Each special depot is for the accommodation of 2,000 or 4,000 men.

The physical therapeutics under consideration include electricity, hydrotherapy, massage, exercises, training, and marching. The three forms of current were employed. The committee of the Royal Society of Medicine on balneology assisted in converting an ordinary hut into a good hydrotherapeutic establishment. The pool bath at 94° Fahr. would hold twelve men sitting up to their necks in that water, in which they usually remained an hour. This was the routine for patients suffering from shock and disordered cardiac action. A whirlpool bath was used for limbs with painful scars or frostbitten; the temperature of this was 110° F. and the water was kept violently agitated; compressed air introduced into the stream provided a bubbling effervescent envelope for the painful limb, which in about 20 minutes was found to be flushed and remained so for hours. It was an excellent preparation for massage, which sometimes could not be borne without it. It could be followed by passive manipulation and the numerous exercises of muscles and joints designed to re-educate them and restore the general physical training.

Lieut.-Col. R. J. Morris remarked that more than a century ago Professor Ling elaborated physical exercises as a definite system of treatment. These exercises he claimed as active or passive again or reduplicated. In these last the work was partially done by the patient, but another person provided resistance. Since November over 76 per cent. of men in his depot had returned to service after physical treatment—massage, gymnastics without apparatus, but by experienced masseurs; also with apparatus, as bicycle, rowing, dumbbells, graduated weights, galvanic and faradic currents, and other means. When his patients could bear more strenuous exercises he passed them on to the army gymnastic staff at Aldershot.

Dr. Bezley Thorne extolled mineralized baths for cardiac rheumatic cases. He had had trench rheumatism cases put on their feet by these which had resisted salicylates and other remedies. Instead of drying after a bath he let patients dry gradually in their blankets. Long emersions should not be given when irritable heart and muscular tremor were present.

Dr. Fortescue Fox thought the preceding reports opportune and valuable. Whirlpool baths were a new feature so nothing dogmatic would be said about them. At high temperatures they assisted immobilized limbs.

Colonel Rodd said the important point was early diagnosis. At the Ramsgate Canadian institution a special board attended to this and in six weeks

quite a number of myopathic and neurasthenic cases were found to have tertiary syphilis; when treatment for this was applied many of the patients were soon back in the firing line.

Dr. Cumberbatch said too little attention had been given to electrical methods, diathermy, and high-frequency currents. Injuries to nerve trunks would need attention for eighteen months or more before the return of some degree of power and the best treatment was by baths supplied with the rhythmically varying, sinusoidal current. His results with this were uniformly good.

Major Turrell said diathermy was of great value. The whirlpool and other baths affected the surface only, but in diathermy the current went directly through the tissues intervening between the two electrodes and could be made to bear on every part of the body. It had been efficacious for relief of acute pain and for frost-bite, was quite safe and warmed the tissues—a good preliminary to massage, it cleared up joint effusions and phlebitis and liberated fibrous adhesions.

Dr. W. Gordon had great faith in hot sand for some forms of injury, more than radiant heat or light in some cases.

Dr. Ackerley had been treating by physical means for more than twenty years, the aim being to overcome defects of circulation by producing active congestion in the part. Pain was sometimes the only obstacle to movement and must be met in the best way. Active movements could not be borne at first.

The July meeting of the new Dermatological Society was devoted to the exhibition of cases. Dr. D. Vinrace showed one of diffuse cellulitis following syphilis, contracted four years ago by a man of forty. He had had four doses of salvarsan and fancied himself cured. Last December he consulted Dr. Vinrace for a diffuse cellulitis in his neck, for which he had taken neosalvarsan and later galyl. The swelling subsided very slowly. Both mercury and iodide of potassium were administered.

Dr. Vinrace also showed a case of leukoplakia in a man. He, too, was about forty. A similar case was shown by Dr. Vinrace some weeks ago. It came on gradually and subsided slowly. The patient had had gonorrhea but not syphilis. He was a very nervous man and a great smoker. Dr. Eddowes, in the chair, thought the tests for syphilis should all be applied as the man might be suffering from a condition left by that disease. Leucoplakia used to be called the "smoker's patch," and that smoking aggravated it he had no doubt.

Dr. Eddowes then showed a case of urticaria pigmentosa, macular form, in a girl of twelve. It contrasted forcibly with a case lately shown by Dr. Samuels. The president repeated an opinion he has often expressed to the effect that rich, hot, fatty food was a cause of urticaria. The mother declared that fat made the girl bilious and gave her heartburn.

The Nonoperative Treatment of the Accessory Sinuses.—Lewis A. Coffin has abandoned the idea of curing diseases of the sinuses, either by operative or other measures, and is satisfied to produce an arrest under constant treatment. By means of a special apparatus for suction, with or without the addition of cannulas, he exhausts as far as practicable the air in the sinuses, beginning with low pressure with resulting escape of mucus, and thereupon forces into the cavities under a pressure up to ten or fifteen pounds air medicated with nebulized oil, iodine and the Bulgarian bacillus. He also gives a course of autogenic vaccine treatment. In two chronic cases he appears to have produced relative recovery.—*Virginia Medical Semi-Monthly.*

OUR LETTER FROM ALASKA.

(From Our Special Correspondent.)

FEAST TO THE DEAD—CHILDBIRTH—NAMING THE BABY—PUBERTY—MARRIAGE AMONG THE ESKIMO.

St. Michael, Alaska, April 30, 1916.

Some of the Eskimo thoughts are very beautiful, as for example "The Feast to the Dead," and some of their acts are strange and very unnatural even in comparison with those of the lower animal. A good example of the latter is the care of their children.

There is usually in each village a squaw who claims to be versed in matters of midwifery, and she attends the mothers in confinement. The most capable midwife in this connection is the one who does the least work and who interferes with Nature the least. It used to be customary for primiparæ to be considered unclean, and as such they were put off by themselves until the child was born, food being handed to them through a crack, but never a word spoken. This custom is passing away with the Eskimo of the lower Yukon. The newborn babe may or may not be wanted. Formerly it was the custom to kill many of the female babies, as they were considered food consumers and in return produced nothing. If it is decided to kill the female baby it is taken out on the tundra or far out on the ice, the mouth filled with snow and left there to freeze to death. It was the custom to kill these females at any time up to the age of five years if it was decided that the child was a burden. This custom fortunately seems to be passing away, and certainly is not tolerated where there are civil authorities.

The baby is named. If born in a village the child is given the name of the last person who died there. In doing this they believe that the spirit of the dead person leaves the grave and enters the child. It now behooves the relatives of the dead person to contribute to the support of the infant as will be spoken of in describing the "Feast to the Dead." The Eskimo believes that spirits or shades ("tagunuhak" as he calls them) preside over everything, and believing this he makes every attempt to avoid offending them as the shade would bring disease upon him, make him have bad luck with the seal, tomcod, white whales, etc. For the same reason the native never punishes a child after it is named until the child is large enough to care for itself. At this time the spirit of the dead ceases to act as a protectorate, so in slapping a child about the age of twelve they will not offend the shade. If the baby is born in camp it is named for the first object the mother sees after its birth, as for example, a tree, mountain, etc.

Apparently the Eskimo care very little for their young. They are filthy, poorly clothed, and without a diaper. They are transported in the hood of their mother's parka, and it is a common sight to see the child's nose bleeding from striking its head against the neck of the mother. The mother usually nurses the child until it is about three or four years of age, and one will sometimes see a mother nursing both a baby and a two-year-old child. They nurse their young until the young can eat raw tomcod or dried salmon fish and sop seal oil with their fingers. The babe of an Eskimo squaw is not kept as clean as a Malamute will keep her pup. Another example to show how little they care for their young. A midwife will sometimes see a baby that she would like to have, if so, will put it under her parka and carry it away, regardless of how it is to be fed. Anteso-

luck, "Cyndrock Mary, the Reindeer Queen," was the midwife for a squaw at St. Michael and took quite a fancy to the baby. The following day she wrapped it up and packed the baby sixty miles by dog team to Unalakleet, with the weather below zero, and raised the child. This is permissible with the native.

When a girl reaches the age of puberty she is considered unclean, and must remain in a corner of the house for forty days. She must have a hood on, hair streaming over her face, and face turned toward the wall. In some places she is kept only four days in this position and then behind a grass mat. The native speaks of her as being "agulingagak," meaning "has become a woman." Should a man come close enough to her during this time to be touched, he is supposed to become visible to all the animals, so that when he goes hunting he will have no luck as the animals will see him. At the end of the period in which she remains in seclusion the girl takes a bath and puts on entirely new garments. She is now ready to become a wife. If no suitors approach her in a reasonable time the father gathers together much food and has a festival (coming out party of better society) to announce that his daughter is ready for marriage.

When the Eskimo sees a girl that he desires to marry he tells his father, who in turn has an interview with the girl's father. If the match is approved of, the young man puts on the very finest clothing that he can get and goes to call. He also takes the finest suit of clothing he can get for the girl, and she dresses up in it. Then they are man and wife according to the native belief. If there are no children in one of either of the parents' families the newly married couple goes to live with that family. Child betrothals are common and take place in one of two ways. The mother of the girl, regardless of the age, may take a boy to live in her home to become the girl's husband when they grow up, or a girl may leave her home and be adopted by a boy's mother for this purpose. There is evidence to show that two native men of different villages sometimes become bond-fellows, and when one goes to the other's village he is given the privilege of his bond-fellow's bed and wife. The children of these kind of families call one another "katknun."

Annually the "Ihlugi," or "Feast to the Dead," is held. This is soon after the Bladder Festival and before salmon fishing begins. It is for the purpose of offering clothing, food, and water to the spirits of those who have died within the year. The day before the festival the nearest male relative of the dead to be honored goes to the grave and plants a stake bearing the family totem. If the deceased was a man this is a kyak paddle; if a woman, a wooden dish. This is to call the spirit to the grave where it waits until called to the Kashim, or Council House. No work is permitted in the village during this festival, and the use of any sharp instrument is strictly prohibited for fear of injuring the spirit, as the spirit would bring evil upon the village. Persons who are to honor their dead take an oil lamp to the Kashim at mid-day, light it and place it upon a stake in front of the seat where the deceased was accustomed to sit. This is to furnish light for the shade and is kept burning until the festival is over. The villagers now gather in the Kashim, the relatives bringing food as far as the door, where it is left. An old man seated in the middle of the floor, and beside the main lamp, begins a rhythmical beating on a drum as an accompaniment to his song. This is usually the Medicine Man. The villagers join in as a chorus, but to the white man's ears there is no music to this. The music is to call the spirit, and when it arrives the relatives go to the door and procure a bit of each kind of food they brought. Returning, they throw this upon the middle of the floor and pour water upon it, washing the food through the cracks. In this way the spirit is believed to receive the benefit of the food. The remaining portion of the food is then brought in and distributed to the guests, and with loud stamping upon the floor, shouting, and singing, the spirit is driven from the building not to return until the next "Feast to the Dead." The native is afraid to die if he leaves no one to represent him at these festivities, as he feels that his shade would suffer from destitution.

Progress of Medical Science.

1. Hygiene of the Mind. Benjamin P. Croft.
2. Mental Preparedness. James J. Putnam.
3. The Meaning of the Mental Hygiene Movement. William A. White.
4. The Menace of Mental Deficiency from the Standpoint of Heredity. Henry H. Goddard.
5. The Functions of Social Service in State Hospitals. Hannah Curtis.

1. Hygiene of the Mind. — Benjamin P. Croft discusses the hygiene of the mind more particularly as it applies to the physician, though his suggestions are equally valuable to others. He says he has wondered many times of late whether as practitioners of medicine we are not in danger of forgetting the real significance of the influence of our minds upon the successful conduct of our work, and the better preservation of our physical bodies and those committed to our care. In our constant efforts to cure diseases either by drugs or surgery or both we are prone to forget how important the influence of a proper control of the emotions is. History teaches that the loss of emotional control has in some instances resulted in death, and there are on record many instances of the effect of emotion on the various physiological functions. There seems to be no question as to the need of regular systematic mental and physical diversion from one's usual occupation. In discussing this proposition the essayist considers what benefits may be derived from outdoor occupations, such as golf, agriculture, geology, etc., and from the relaxation of literature. He thinks that the mental relaxation and stimulation of friendship is one of the benefits we are losing out of our busy modern lives. Above all, he emphasizes the importance of attaining and keeping an attitude of mental optimism. This mental habit should be cultivated early in life; but it is never too late to begin.

2. Mental Preparedness. — James J. Putnam states that the European war—its causes, its emotional history, its probable results, the obligations of America with reference to international affairs—relates very naturally to mental preparedness. The question therefore arises as to how we shall make our children and ourselves mentally more stable and to what end we should seek mental stability. The principles chiefly significant are that the human race, as a whole, undoubtedly does move toward a type which we can represent to ourselves ideally, though only ideally. This is the goal of ideal perfection. The evidence is strong that an influence is actually at work that indicates the existence of such a goal and points the way toward it. This influence is opposed by the tendency to reversion, and the problem of helping our children resolves itself

into how we can best neutralize this tendency. The author discusses how this may be done through a proper direction of the elemental passions, through a recognition that the same forces are immanent and vital in the child that have brought mankind to where it is and that will carry it still farther. If the child is to progress toward the goal of social companionship and usefulness, three things must be properly directed, egoism, love, and imagination. If the European war has taught us anything it is that highly organized social efficiency is indispensable for the ultimate success of civilization and the attainment of human ideals.

3. **The Meaning of the Mental Hygiene Movement.**—William A. White points out that in primitive communities many courses of action were tolerated which would not be endured in a civilized community; that in a civilized community one cannot do anything that he may happen to choose without crossing the path of some one else. The group of people who are called insane are those who exhibit a type of conduct that cannot be tolerated in the community in which they live. The characteristic of this type of conduct is social inefficiency. There are many different kinds of socially inefficient conduct, as for instance the pauper, the criminal, the neurotic. They all have one characteristic in common; they cannot adjust themselves to their social environment. A proper environment means a great many things and can only be obtained in an institution where the problems regarding these different types of people should be worked out, and they should be worked at until solutions have been reached which are sufficiently valid, sufficiently correct, sufficiently definite and far-reaching, to be backed up by the community and formulated in some sort of statute. The institution conducted on scientific principles aims to provide an environment in which these people who cannot adjust themselves to the community can find their best personal expression, and an environment in which they can pay back what they are getting from the community. The writer thinks we shall never entirely solve the problem of the mentally defective, but we can perhaps make the distance which separates the man at the top of the ladder and the man at the bottom a little bit shorter, by concerted and really tremendous effort.

4. **The Menace of Mental Deficiency from the Standpoint of Heredity.**—Henry H. Goddard emphasizes the fact that the essence and importance of the menace of mental deficiency lie in the rapid propagation of the feeble-minded compared with other classes in the community. Formerly when all stocks were equally prolific and the mentally deficient were more exposed to eliminative accidents, natural process served better to maintain the balance. Now the feeble-minded are more protected by society from disaster, and the steadily declining fertility of the superior stocks tends to destroy this advantage. Optimists believe that the situation will yet right itself; but there seems, nevertheless, occasion for very genuine and serious concern, unless additional measures are taken to correct the disturbance of evolutionary process created by modern protective measures, which favor the survival of the unfit, and by modern practice which limits artificially the number of fit who survive. Broadly speaking corrective measures may be of two kinds—those which tend to restrain the inferior, and those which tend to increase the superior stocks. Dr. Goddard emphasizes the former, but calls distinct attention also to the latter.

10. The Value of Iodine in Gonorrhea. M. Abramovitz.

2. **The Physiological and Toxic Action of Formaldehyde.**—Samuel E. Earp discusses the physiological action of formaldehyde, and reports three cases of poisoning from formalin. Two of these were accidental and one was due to an attempt at suicide. All recovered, though the first patient was moribund and there was apparently no possibility of recovery. The treatment consisted of the administration of a quart of milk by the stomach tube after the stomach had been washed by diluted aromatic spirits of ammonia, which is supposed to be the only antidote for formaldehyde. Milk of magnesia was also given. As a stimulant sulphate of strychnine was administered according to the requirements of the case. These cases are reported to call attention to the danger of this agent which is used commercially with hardly a thought of its being harmful.

3. **Fever, a Part of the Syndrome of Toxemia.**—Francis M. Pottenger recalls that in attempting to classify the symptoms of tuberculosis he has suggested that those belonging to the toxic group were, for the most part, an expression of general discharge through the sympathetic nervous system and that they were caused by the action of toxins upon the central nervous cells. In this manner he has accounted for the rapid heart action, lack of appetite, coated tongue, deficient secretion on the part of the stomach and other glands of the intestinal tract, particularly the liver and pancreas, and for the deficiency in motility on the part of the stomach and intestinal tract. He accounted for the symptoms of malaise, lack of endurance, and nervous irritability as part of the same picture. Further study has led him to believe that fever, too, belongs to this same group, and instead of being considered an entity should be considered as one of the symptoms of toxemia. His theory briefly put is that fever is due to the action of the toxins on the nervous system. It arises largely from constriction of the superficial vessels interfering with heat dissipation. Its production is a part of general sympathetic stimulation. The collapse which results from excessive toxic action is due to a vasodilation, a temporary or permanent vasomotor paralysis, and is accompanied by perspiration, rapid dissipation of heat, and subnormal temperature. This theory would also account for the fever which follows various depressive emotional states.

4. **Typhoid Fever.**—I. L. Nascher reports two unusual cases of typhoid fever. The first was irregular in its onset and course, the symptoms in the first place being rather indicative of a lobar pneumonia. The subsidence of the symptoms referable to the chest and the persistence of diarrhea toward the end of a week led to the suspicion of typhoid fever. Although text-books say there is no eruption after the fourteenth day, in this case the typical typhoid spots appeared in the third week. Delirium occurred on the twentieth day and for several days thereafter. The severe typhoid state began at this time and lasted for about a week after. The second case, a daughter of the first patient, aged thirteen years and weighing 130 pounds, had the disease, which ran a fairly typical course for about a month when she developed signs of pulmonary involvement, although there had been no chill, cough, pain, expectoration, or any of the usual symptoms of pneumonia. From this time until the patient died, some eight weeks later, there was no relationship between temperature, pulse,

and respiration, there being frequently a marked rise or fall in temperature, pulse, or respiration, without any apparent cause. There was a persistence during the entire time of four groups of symptoms—gastric, intestinal, pulmonary, and cerebral. There was a frequent absence of correspondence between symptoms and physical findings. There was an improvement in the temperature, pulse, and respiration toward the end. There seemed to be two and perhaps three distinct infections —typhoid, pneumonia, and septic. During the course of her illness the patient vomited pus, and pus came from the rectum and vagina. Autopsy revealed a unique condition. There was a pus reservoir lying between the transverse colon and the diaphragm; perforation of the diaphragm upward into the pleural cavity; no pathological condition in the lungs, except adhesion of the lower lobe of the left lung to the diaphragm; there were widespread adhesions and necrotic areas in various organs and tissues, and the second and third lumbar vertebræ were denuded. There was absence of perforation of the vegina or of any other assignable cause for the presence of pus in the vagina. The liver was enormously enlarged, weighing five and three-quarters pounds. Both kidneys were also enlarged.

7. **Chronic Suppurative Otitis Media.**—Hugh B. Blackwell reports sixteen cases in which he has performed the following operation: He makes the usual postaural incision, as in the Stacke operation. The soft parts anterior to this incision are elevated and retracted forward; the cortex is removed with a gouge and the subcortical cells with curettes until the antrum is opened; the posterior bony canal wall is lowered and the antrum widened to its fullest possible extent. When the short process of the incus becomes visible, the external attic wall is removed by placing the back of the curette external to and in front of the incus and curetting from within outward. The bony canal wall is still further lowered until the facial ridge is reached, leaving only an epitympanic ring in its superior portion, with a width of about one-sixteenth of an inch. In four instances I have removed this ring in the superior and outer quadrant of the circle, leaving the membrana typmani and ossicles intact. The granulations, polypi, and cholesteatoma lying in the external and internal attic are removed by curetting internal or external to the incudal body, care being observed not to destroy the suspensory ligament of the malleus or its external lateral ligament. In curetting near the incus great care must be taken not to disturb the ligament which binds the extremity of its short process to the bone below and just in front of the external semicircular canal. The drum and ossicles are of course not removed, but left *in situ*. An L-shaped metal flap is cut, as in a radical operation, the cartilage removed, and the flap sutured to the temporal fascia. The mastoid wound and attic region are packed snugly, thereby furnishing support to the flap, and the posterior wound is sutured. The author does not present this operation as one that would entirely replace the radical procedure, but is convinced that when a proper selection of cases is made it will yield even better functional results as well as a dry ear.

3. **Fat Embolism in Bone Surgery.**—Edwin W. Ryerson relates several cases of fat embolism that have occurred in his experience which lead him to believe that this is a much more frequent and serious danger in bone and joint surgery than he had supposed. He reviews the various methods that have been proposed for the treatment of fat embolism, and states that these are apparently not on a well-defined basis and cannot be considered as having any curative value in cases in which a large quantity of fat has been forced rapidly into the lungs. It seems likely that a complete stasis of the circulation during and a short time after the operative procedures would probably prevent or at least reduce the transportation of the fat through the venous channels. The tourniquet can be left in place as long as half an hour, and can then be gradually loosened. Animal experiments show that fractures and contusions of the bones cause much more embolism than does the performance of a typical Albee bone transplant to the spine. The use of the chisel and mallet is far more dangerous than the motor saw. The experiments also showed that when a tourniquet was applied the fatty embolism from all kinds of traumatism to the bones was markedly decreased. The tourniquet should be made a matter of routine in bone surgery.

4. **The Evolution of Osteochondritis Deformans Coxæ Juvenalis.**—Albert H. Freiberg calls attention to a deformity of the femur occurring in children which in its later stages bears much resemblance to that seen in so-called arthritis deformans of the adult. The most striking difference, however, is seen in the absence of new bone formations, or osteophytes, in those portions of the joint peripheral to its bearing surface. In its symptoms also the disease of early life differs from that of the adult, being in the former of much milder character and often of such insidious course as to escape detection until the terminal deformity has been discovered. It seems quite evident to-day that these juvenile cases have in their earlier stages, and in former years, constituted largely the class of cases which were formerly regarded as mild hip tuberculosis. Here may be found the explanation of the remarkably complete restoration of function in cases of hip disease which were formerly brought forward from time to time as evidence of the efficiency of this or that method of treatment. A roentgenological study of these cases identifies them with the disease accurately described by Perthes. The writer believes it is logical to assume, as an etiological basis for osteochondritis deformans juvenalis, a chronic infectious process of probably secondary character, just as is done in explaining other deforming joint dseases of later life.

5. **Effective Localization of Bacteria in Diseases of the Nervous System.**—Edward C. Rosenow.— (See MEDICAL RECORD, July 1, 1916, page 31.)

6. **Poliomyelitis, with Some Observations on Thirty Cases.**—Archibald L. Hoyne and Frances P. Cepelka state that the cases in this series were, with a few exceptions, of a mild type and there were no fatalities. Two of the cases were of the encephalic variety, all the others being spinal. Eighty-six and two-thirds of the patients were under five years of age. There were fourteen boys and sixteen girls. Practically all the children were fair-haired, there being but one really dark-complexioned child in the series. Where the pa-

tient was received early, following lumbar puncture, from 0.5 to 1 c.c. of 1:1000 epinephrin chlorid solution was given intraspinally. This was repeated every four to six hours, provided the pulse rate did not exceed 160. In no case was the dose repeated more than three times. Some patients showed marked improvement in from one-half to one hour following the injection. Such marked improvement was seldom permanent, but gradual improvement in some instances seemed to be more rapid. The authors draw the following conclusions: (1) There is still some unknown agency responsible for the transmission of poliomyelitis. Not every case is acquired through direct contact or by means of a human carrier. (2) A leukopenia is not characteristic of poliomyelitis, since a leukocytosis was present in almost every case observed by us. (3) In order to control an epidemic or an impending epidemic, isolation by means of compulsory hospitalization will give the best results. (4) An isolation period of three weeks from the date of attack is probably sufficient.

7. **Municipal Control of Infantile Paralysis.**—Abraham Sophian, who was special Commissioner of Health for Bridgeport, Conn., in charge of prophylactic measures against infantile paralysis, gives the result of this experience. He says that, following the outbreak of the epidemic in New York, cases immediately occurred in neighboring cities that had close business relations with New York and in some of these cities the epidemics were very large. The relatively larger number in other cities as compared with Bridgeport indicates that active preventive measures are important. The preventive campaign as planned and carried out in Bridgeport may be classified as follows: (1) Quarantine of the sick and healthy contacts. Quarantine of the sick should be rigid and, until we learn more about the disease, should cover the probable period of the epidemic, about eight weeks. (2) Exclusion of probable carriers from New York and adjoining cities in which the disease was epidemic. (3) Establishment of a special central hospital to which was enforced compulsory removal of all patients with infantile paralysis. (4) Organization of a special medical "poliomyelitis diagnosis squad." (5) Repeated circularization of the physicians, calling attention to abortive cases and the preparalytic stage of the disease. (6) Mobilization and enlargement of all the sanitary forces covering the street-cleaning department, garbage department, police and fire departments, regular sanitary inspectors, and the staff of nurses.

8. **Gastrointestinal Findings in Acne Vulgaris, Especially Fluoroscopic.**—Lloyd W. Ketron and John H. King present an analysis of thirty cases of acne vulgaris which were subjected to a fluoroscopic examination of the gastrointestinal tract; the patients also received test meals, and analysis of the gastric contents was made. It was found that 93 per cent. showed gastric abnormalities and 70 per cent. showed intestinal abnormalities. The most common gastric findings were hyperacidity, 48.1 per cent.; retention, 36.6 per cent.; atony, 33.3 per cent., and ptosis, 40 per cent. The most common intestinal findings were cecal stasis, 46.6 per cent.; ptosis of the colon, 36.6 per cent., and right lower quadrant adhesions, 23.3 per cent. Clinically, 62.3 per cent. of the cases gave evidence of gastric disturbances and 40 per cent. of them were constipated. None of the cases examined gave entirely normal gastrointestinal findings, and 60 per cent. of the cases showed abnormalities which were of such a nature as to permit gastric and intestinal stasis, followed by toxic absorption. The conclusion seems evident that while there are a number of predisposing factors to this disease, one of the most important is gastrointestinal derangements.

The Lancet.

August 5, 1916.

3. **An Address on the Tuberculous Soldier.**—William Osler states that the Allied armies in the west have been singularly free from camp diseases; the common civilian diseases, however, have had their innings, and have played relatively the more important rôle. The soldier takes with him into camp two great enemies—the tubercle bacillus and the pneumococcus. The proportion of tuberculous individuals is much less than among civilians. In 1915, 2770 cases of tuberculosis were dealt with by the Chelsea Boards, but it cannot be said just what proportion this bears to the enlisted force. An inquiry shows that in 13 sanatoriums out of 160 cases 90 were regarded as due to the war; in five other places most or very many out of 84 were attributed to this cause. Of the 2770 cases considered in 1915 only 1641 were granted pensions. The question arises as to what becomes of the remainder. Reviewing the whole situation Osler offers the following suggestions: (1) A more searching examination should be made of all recruits. Doubtful cases should be referred to the tuberculosis expert of the district. Men unfit to be worked up to the soldier standard become simply material for pension claims. (2) Army experts should decide upon the doubtful cases before their discharge. Provision should be made for their study. There are plenty of tuberculosis experts in khaki whose knowledge should be used to put these cases in their proper category. (3) A national organization should look after the welfare of the tuberculous soldier. A roll and record should be kept, and every case supervised with the greatest care. The National Association should undertake this work in cooperation with the Society for the After-care of Soldiers. A small central committee of these two bodies could organize committees in each county and bring official pressure to bear on authorities to furnish the proper hospital accommodation.

4. **Acute Intestinal Obstruction.**—George F. Aldous presents notes on ten cases of acute intestinal obstruction, in some of which the causes are common and in some rare. In dealing with these cases he emphasizes the importance, first of early operation, and, secondly, of one or more enterotomies to reduce toxemia. He admits that it is occasionally difficult to make a diagnosis but is sure that it is safer to open the abdomen when acute symptoms are present than to wait.

6. **Extraction of Bullet from Middle Mediastinum.**—L. E. Barrington-Ward recounts the case of a soldier sent back to England six weeks after having received a wound of the chest, which had healed. The man appeared to be healthy when at rest. Exercise gave him sharp pains over the precordia and breathlessness. A radiogram showed a bullet apparently lying in the pericardium near the left border of the heart just above the diaphragm. On screening, movements of the bullet due to cardiac and respiratory excursions were well seen. At operation an incision was made in the midline of the sternum from the level of the fifth costal cartilage downward to the sixth costal cartilage, and then along the sixth costal cartilage outward. The

sixth costal cartilage was removed. The left lung and pleura were pushed aside; it was thus found that through this incision it was possible to palpate thoroughly the heart and explore the pericardium. At a depth of about 4 inches from the surface the bullet was found adherent to the pericardium and also to the pleura and the lung. It lay surrounded by a few beads of pus with its long axis applied to the pericardium, apex forward. The bullet was extracted, the pericardium closed with fine catgut, the muscles brought together, a small rubber tube inserted superficially, and the skin wound closed with Michel's clips. Among the points of interest in this case were the comparative freedom with which the heart and pericardium could be examined without embarrassment under inhalation anesthesia and the possibility of separating the pleura off the pericardium without any recognizable collapse of the lung taking place.

1. Notes on Military Orthopedics. VI. Disabilities of the Knee Joint. Robert Jones.
2. Further Observations on the Treatment of Gangrene by Intravenous Injection of Hypochlorus Acid (Eusol). John Fraser and H. J. Bates.
3. Convalescent Paratyphoid and Dysenteric Cases Considered from the Preventive Standpoint. I. Walker Hall, D. C. Adam, and R. E. Savage.
4. Treatment of Scabies by Sulphur Vapor. John Bruce and Stanley Hodgson.
5. The Economical Use of Solutions of Costly Alkaloids for Ophthalmic Purposes. N. Bishop Harman.

1. Disabilities of the Knee Joint.—Robert Jones gives a broad classification of these derangements and disabilities, with their diagnostic signs, and indicates appropriate lines of treatment. He points out that there are three common conditions which are not always as clearly distinguished by practitioners as they might be. They are: (1) Simple sprain of the lateral ligament, usually the internal; (2) slipping of the semilunar cartilage, and (3) nipping of the infrapatellar pad of fat. All of these injuries are associated with effusion of fluid into the joint, and in all the patient complains of more or less recurring disability after the lesion. Simple sprain of the internal lateral ligament is marked by a special tender spot over the attachment of the ligament and nowhere else. A joint which has been the seat of a definite injury will generally fill up with synovial fluid when first used. Therefore the application of a pressure bandage should never be omitted. If the knee is carefully brought into use by graduated exercises each succeeding day there should be less effusion. If the effusion does not become less the patient is using the knee too much. The author's experience of operations on the internal semilunar cartilage covers some 2,000 cases, on the basis of which he states that the knee should never be opened except under the most scrupulous aseptic conditions, and never in a hospital where there are a large number of septic cases. The procedure which he prefers is to place the leg so that it hangs over a table at right angles to the thigh. The knee is wrapped in sterile gauze soaked in biniodide solution. The incision is made through the gauze. A second clean knife should be used for the deeper dissections. The incision is made over the anterior end of the cartilage, nearly but not quite parallel to the upper edge of the tibia. Great care should be taken never to allow the incision to extend far enough to the inner side to cut any fibers of the internal lateral ligament, since this is a fault that leads to weakness of the knee lasting for months or years, and is still frequently met with in cases which have been operated on by the old, large J-shaped incision. In removing the whole cartilage great care should be taken that no tags of cartilage are left projecting from the attachment to the coronary ligament, as these frequently give rise to continued symptoms, due to nipping or adhesions. No movement of the knee must be allowed after the incision has been made, as this may favor the entrance of air. It is not until the stitching is complete and pads placed over wound that the knee is straightened. If the operation is performed with a tourniquet around the thigh no vessels need be tied, and if elastic pressure is applied before the tourniquet is removed there need be no fear of bleeding into the joint. A knee cage is presented which is useful in protecting thickened retropatellar pads of fat, and emphasis is placed on the importance of providing for the restoration of the quadriceps muscle, which is wasted and weakened in all these injuries to the knee.

3. Convalescent Paratyphoid and Dysenteric Cases Considered from the Preventive Standpoint.—I. Walker Hall, D. C. Adam, and R. E. Savage have reported their findings in a large number of typhoidal and dysenteric convalescents examined during the last eight months, the investigations in each case consisting of the estimation of the agglutination content of the blood, the microscopical examination of the stools, and cultural isolation from the urine and feces. The cases grouped themselves into three batches. The first extended from September to December, 1915, and contained some acute and subacute infections. There were 297 cases in this group, convalescent from four to twelve weeks, and bacilli were present in the excreta in 3.7 per cent. The second group covered the period from December, 1015, to February, 1916, and comprised cases of early convalescence. There were 156 of these and bacilli were found in the excreta in 1.3 per cent. The cases comprising the third group came in from February to May. There were 217 cases, all apparently fit for work again, and bacilli were not present in the excreta of any of these. The above groups were all paratyphoid convalescents. There were 605 dysenteric convalescents examined, and bacilli were found in the excreta of 1.1 per cent. In the paratyphoid cases *E. histolytica* was present in 10.06 per cent.; in the dysenteric convalescents, in 6.68 per cent. The fact is brought out that in convalescents from dysentery, typhoids, paratyphoids, and probably other conditions, there is protozoal infection to an equal extent. The average time required for the disappearance of *E. histolytica* from the feces was 22.9 days, but one case has yielded positive findings for 125 days already. It was found that the date of disappearance of the bacilli from the excreta of typhoid and paratyphoid convalescents varied from eight to fifteen weeks from the time of the onset of the attack, and in the dysentery convalescents the time of disappearance of the bacilli varied from eleven to fourteen weeks from the time of onset of the disease.

4. Treatment of Scabies by Sulphur Vapor.—John Bruce and Stanley Hodgson say that in the treatment of a considerable number of cases of scabies the ordinary treatment by sulphur ointment is slow. For the past twelve months they have given sulphur dioxide gas a trial and have found that it meets their requirements. The treatment is given in a cabinet constructed along the lines of a home Turkish bath. The seat provided for the patient consists of three narrow cross-bars placed 30 inches above the level of the floor. This enables the fumes to reach all portions of the buttocks and nates. The patient is first well scrubbed and then placed in the cabinet and allowed to remain for fifty minutes. The writers have treated over 200 cases and have had about 2 per cent. returns, and in these instances they think some article of clothing escaped disinfection.

5. The Economical Use of Solutions of Costly Alkaloids for Ophthalmic Purposes.—N. Bishop Harman recommends the following as an "ophthalmic solvent" for cocaine, etc., since it is more satisfactory in the preservation of solutions than others in common use:

Distilled water	1 pint
Methyl salicylate	2 grains
Oil of gaultheria	2 minims
Tincture of iodine	2 minims

The mixture is well shaken, poured into a stoppered bottle, and left for forty-eight hours, when it is ready for use. As watery solutions are wasteful and unsatisfactory, the solution may be thickened with gum arabic until the solution is so viscid that it will cling in a fair round drop on a small lacrymal probe. It has been found that cocaine, atropine, and homatropine are equally effective in this gummy solution, and the economy of their use is noteworthy.

Le Progrès Médical.

July 20, 1916.

Sulphohydrargyric Medication. — Loeper, Bergeron, and Vahram refer to the great number of so-called rheumatic ailments among the soldiers, at least one-eighth of all who are invalided from active service being of that type. But while exposure, cold, dampness, fatigue, and trauma may be responsible and may play some part in the genesis of these affections, infections and anomalies of metabolism are even more at fault. It must not be forgotten that these causes of rheumatism act upon a syphilitic soil. In a special research the authors have found forty-one cases of rheumatism in the causation of which syphilis played a predominating rôle. This material represents about one-third of all the doubtful cases. The diagnosis of syphilis was based on positive work, coexistent lesions of syphilis, history, and the success of antiluetic measures. Certain cases of frankly syphilitic and tabetic arthropathy are not included in this series. Of this series twenty-five cases were in the tertiary stage, early or late. Syphilis appeared as an arthralgia four times, as polyarticular arthritis eight times, as "white swelling" four times, as hydarthrosis five times. Arthritis sicia was present in eleven patients and deforming rheumatism in ten. Two patients were probably heredosyphilitics, and twenty others denied infection. When syphilis is thus completely masked by rheumatoid lesions, a combined plan of treatment appears indicated. The authors obtained two complete cures with neosalvarsan alone and six others with injections of biniodide of mercury. Still others yielded to ordinary mercurial treatment by mouth. Finally there were cases refractory both to salvarsan and mercury. Since colloidal sulphur is now being widely tested on ordinary rheumatism, the authors made use of a colloidal association of mercury and sulphur. No combination of any sort results. In twenty cases thus treated seventeen showed improvement. There were five complete recoveries. The manifestations following the injections were slight and sufficiently like those following the injection of sulphur alone. We have, in fact, a new form of "mixed treatment" for these hybrid cases.

Le Progrès Médical.

August 5, 1916.

Cancer of the Stomach; Metastasis to Cerebellum; Terminal Meningitis.—De Fortunet and Cade sum up their remarkable case as follows: The patient was but 31 years old when he appeared with cancer of the stomach. Instead of the rapid evolution of the growth which is usually anticipated at such an age, its course had been extremely torpid and its actual onset was probably several years earlier than the earliest symptoms. Throughout the patient's disease he remained in good health until near the end. The nervous phenomena which announced the metastasis were extremely complex and conflicting. The course was rapid and suggestive of meningitis, although fever was absent; it also suggested generalization of a meningoencephalitic process. Cytological examination of the cerebrospinal fluid showed a slight opacity and increase of tension. The cell content was rich, comprising polynuclears, lymphocytes, endothelia, and especially large cells regarded as coming from a neoplasm. Autopsy showed cancer on the posterior aspect of the stomach, submucous infiltration, extension to pancreas, lymphatic generalization, a secondary nodule seated superficially in the inferior portion of the left lobe of the cerebellum. In the same locality there was purulent meningitis. The gastric neoplasm was of the extreme scirrhous type. The patient, a soldier, had been interned for a supposed tumor on the anterior aspect of the stomach. It was readily palpable, hard, and irregular in shape. Patient vomited continuously, and his general condition was bad. Examination failed to reveal thoracic anomalies, ascites, melena, etc. Aside from the tumor there was a gland paquet in the supraclavicular region. He had complained of his stomach for the past five or six years; nevertheless he had kept up with his duties until the time of transfer to the hospital. A diagnosis was made of the malignant growth of the stomach, inoperable. A few days after his internment nervous manifestations supervened, all the extremities becoming paralyzed and contractured. A comatose state next set in. Death occurred even before a clinical diagnosis could be made, although study of the punctate led to the opinion of a neoplastic meningoencephalitis independent of autopsy finds.

Systemic Disturbances from Pyorrhea Alveolaris.—B. P. Rivers, Jr., intimates that gastric ulcer and appendicitis as well as postoperative pneumonia may sometimes be traceable to Rigg's disease. Aside from these local infections a general run down state may have the same cause and disappear after thorough cleansing of the teeth. The symptoms presented by a single patient, a woman of forty, comprised the following: loss of appetite, bad taste in the mouth, excessive flow of saliva, pain in the stomach after eating, burning sensation in the empty stomach, morning nausea. Every afternoon she felt feverish, languid and tired. There were frequent attacks of constipation and diarrhea and much flatulence. There had been loss of weight. The mental state was poor, melancholic. The mouth was in a very bad shape because bleeding gums prevented the use of the tooth brush. She had recurrent attacks of tonsillitis. Blood tinged pus could be squeezed from the gums. The woman could not do her work as school teacher and believed herself about to die in a short time. Cases like this are not uncommon.—*Kentucky Medical Journal.*

The Energy Index of the Circulatory System.—Barach states that changes in the activity of the circulatory system are accomplished by the adjustment of three factors, maximum pressure, minimum pressure, and pulse rate. Since these are measurable factors a calculation based on the triad should indicate the total energy expenditure of the circulatory system. The product of such a calculation based upon this triad should indicate the total energy expenditure of the circulatory system. The product of such a calculation, which I term the energy index, under normal conditions represents a kinetic force *per minute* equal to not over 20,000 mm. Hg. pressure.—*American Journal of the Medical Sciences.*

Book Reviews.

THE INTESTINAL PUTREFACTIONS: CLINICAL STUDIES OF ENTEROCOLITIS. By CHARLES FREMER RECKHAM, M.D. Price, $2.00. Providence, R. I.: Snow & Farnham Company, 1916.

THE intestinal putrefactions have been greatly in evidence during recent years and their study has been elaborate and painstaking. A good deal has been learned on the subject and perhaps a good deal has been conjectured. However, that intestinal putrefaction is responsible for many conditions of ill health cannot be denied and therefore it is well that physicians and surgeons should be acquainted with the best means of fighting it. Dr. Fremer has written a practical book, which contains a considerable amount of valuable information, a book which should prove useful for reference.

PLAGUE. ITS CAUSE AND THE MANNER OF ITS EXTENTION—ITS MENACE—ITS CONTROL AND SUPPRESSION—ITS DIAGNOSIS AND TREATMENT. By THOMAS WRIGHT JACKSON, M.D., Member American Red Cross Sanitary Commission to Serbia, 1915; Lately Captain and Assistant Surgeon, U. S. Volunteers; Lately Lecturer on Tropical Diseases, Jefferson Medical College; Member Manila Medical Society and Philippine Islands Medical Association, etc. With bacteriological observations by Dr. OTTO SCHÖBL, Bureau of Science, Manila. Illustrated. Price, $2.00. Philadelphia: J. B. Lippincott Co., 1916.

THE author of this work writes with authority since for two years he was in charge of all plague suppressive measures in Manila. The book in as far as it is a personal one is of great value and extreme interest and contains such an amount of odd facts in connection with the rat problem as to give it a status as a faunal authority. The author lives strictly up to his title, so that the pathology and symptomatology are practically excluded. The work should doubtless be classed under the head of sanitation and should prove to be most valuable to all who have to do with public health matters.

BLOOD PRESSURE—ITS CLINICAL APPLICATIONS. By GEORGE WILLIAM NORRIS, A.B., M.D. Assistant Professor of Medicine in the University of Pennsylvania; Visiting Physician to the Pennsylvania Hospital; Assistant Visiting Physician to the University Hospital; Fellow of the College of Physicians of Philadelphia; Member of the Association of American Physicians, etc. Second edition, revised and enlarged. Illustrated with 102 engravings and one colored plate. Price, $3. Philadelphia and New York: Lea & Febiger, 1916.

DR. NORRIS' work on blood pressure is the second edition in less than two years. On October 24, 1914, the first edition was reviewed in these columns and the one just issued has been thoroughly revised, and contains several notable additions. In fact, the somewhat voluminous literature on the subject has been sifted and the author has incorporated the salient features in his present work. Books dealing with blood pressure are welcome as they all add something to our incomplete knowledge of the matter for the significance of the variations in blood pressure is not altogether understood as yet. There is a certain amount of confusion between cause and effect. However, works like the one before us, written concisely and clearly, will serve to elucidate the obscure points or, at any rate, will present all that is known concerning blood pressure in easily intelligent language. The chapter dealing with blood pressure in arteriosclerosis is, perhaps, especially worthy of attention. The work is well got up and adequately illustrated and may be recommended as likely to be of practical use to the busy practitioner.

THE JOHNS HOPKINS HOSPITAL REPORTS. VOLUME XVII. Baltimore: The Johns Hopkins Press, 1916.

THIS volume comprises eight monographs, each of which merits a separate notice. The most compendious of these is the Statistical Experience Data of the Hospital from its inception in 1892 to 1911 by the well-known statistician Hoffman. There are 72 classifications of figures. Nearly 44,000 patients have been admitted, of whom nearly 10,000 were colored. Winternitz in a paper on primary cancer of the liver reports five cases from the hospital records. There appears to be over 150 cases on record, yet the disease is extremely rare in extensive autopsy material. Cancer of the bile ducts is included, and constitutes over one-fourth of the total. Two articles deal with thrombosis —"Free Thrombi and Ball Thrombi of the Heart," by J. H. Hewitt, and "Venous Thrombosis During Myocardial Insufficiency," by Sladen and Winternitz. Two further articles, largely experimental, deal with leucemia—"Benzol as a Leucotoxin," by L. Selling, and "Leukemia in the Fowl," by H. C. Schmeisser. The two remaining papers are valuable anatomical contributions—"The Origin and Development of the Lymphatic System," by Florence R. Sabin, and "The Nuclei Tuberis Laterals and the So-called Ganglion Opticum Basale," by E. F. Malone. The volume is richly illustrated; aside from numerous text figures, charts, etc., there are twenty-three special plates, comprising numerous colored and halftone figures.

A TREATISE ON BLOOD PRESSURE IN OCULAR WORK WITH SPECIAL REFERENCE TO FACTORS OF INTEREST TO REFRACTIONISTS. By EUGENE G. WISEMAN. Illustrated with 19 engravings. Rochester, N. Y.: John P. Smith Printing Co., 1916.

THE author of this book does not appear to be a physician and his book is frankly written to enlarge the usefulness of the optometrist. He expects to be criticized bitterly for his effort, although it does not appear by whom; since if he is not a graduate physician there can hardly be any medical censorship. The book considers in succession the general subject of blood pressure determination, the relation of ocular to general pathology, and the use of blood pressure tests in optometry. The latter section is quite original in conception and execution. Incidentally a table of 100 cases of retinitis and retinal hemorrhage in nephritics is given with blood pressure finds. The author has gone extensively into the classical literature of ophthalmology and general medicine.

THE ENDOCRINE ORGANS. An Introduction to the Study of the Internal Secretions. By Sir EDWARD A. SCHÄFER, LL.D., D.Sc., M.D., F.R.C., Professor of Physiology in the University of Edinburgh. Price, $2.50. London and New York: Longmans, Green & Company, 1916.

THIS book is founded upon the Lane medical lectures delivered by Sir Edward Schäfer at Stanford University, California, in the summer of 1913. These lectures have been revised and published with several appropriate illustrations. The aim of the work is to supply a concise account of our present knowledge of the internal secretions for the benefit of students and practitioners who may be desirous of obtaining more information regarding them than is afforded by the ordinary textbooks of physiology, but have not the time nor opportunity to peruse extensive monographs or consult original articles. The Edinburgh professor has well succeeded in this aim. No one is better fitted to speak authoritatively on the internal secretions than he, and his little work will prove immensely useful to both students and practitioners.

DISEASES OF THE EYE. A Handbook of Ophthalmic Practice for Students and Practitioners. By GEORGE G. DE SCHWEINITZ, M.D., LL.D. (University of Pennsylvania). Professor of Ophthalmology in the University of Pennsylvania; Ophthalmic Surgeon to the University Hospital; Consulting Ophthalmic Surgeon to the Philadelphia Polyclinic Hospital, the Philadelphia General Hospital, the Orthopedic Hospital, and the Infirmary for Nervous Diseases. Eighth Edition. Philadelphia and London: W. M. Saunders Company, 1916.

DE SCHWEINITZ'S Diseases of the Eye had become a household word with members of the medical profession, and its editions have been so numerous that there is little left to say concerning the work. In this, the eighth edition, chapters have been revised in accordance with the latest developments in ophthalmology and the treatment thereof during the past three years. The metric equivalent of the doses of the remedies and the strengths of the solutions has been substituted for the old mode of measuring. Several new subjects are dealt with for the first time, including Clifford Walker's method of testing the visceral field; anaphylactic keratitis; family cerebral degeneration with macular changes; the ocular symptoms of diseases of the pituitary body. A portion of the chapter on iritis has been rewritten and additions and alterations are numerous throughout the book. A number of new illustrations have also been inserted.

Society Reports.

AMERICAN PEDIATRIC SOCIETY.

(Special Report to the MEDICAL RECORD.)

(Concluded from page 439.)

Tuesday, May 9—Second Day.

THE PRESIDENT, DR. ROWLAND G. FREEMAN OF NEW YORK, IN THE CHAIR.

Report of Committee on Vaginitis. — Dr. J. C. GITTINGS, Dr. SAMUEL McC. HAMILL and Dr. C. A. FIFE presented this report which was the result of an investigation which had been in progress several years. It included a summary of the replies to a questionaire sent to a large number of hospitals and homes for children, and formed the basis of a set of recommendations which were submitted for the approval of the society. After a thorough discussion of the subject the Society unanimously adopted the following resolutions which were to be embodied in a letter to health officers: (1) That cities be required to provide adequate hospital and dispensary facilities for the care and treatment of children having vaginitis. (2) That matrons be placed in charge of girl's toilet rooms in public schools. (3) That toilet seats embodying the principle of the U-shape be used in all schools and that the toilets be of proper height for different ages. (4) That city and state laboratories be empowered and equipped to make bacteriological examinations for physicians when patients cannot afford to pay a private laboratory fee. (5) That educational literature on the subject of vaginitis be prepared and distributed to mothers through the medium of physicians, hospitals, dispensaries, health centers, municipal and visiting nurses. That asylums for children and day nurseries be licensed, and that the license be not granted unless: First, the institution has adequate facilities for the recognition of gonococcus vaginitis; and second, that the institution exclude children having this disease if they could not be properly isolated.

It was further recommended that the American Pediatric Society address a letter to hospitals which should contain the following recommendation: (1) That separate wards be maintained for the treatment of children with vaginitis who were also suffering from other diseases. (2) That microscopic examinations of smears be made before admission to the general wards of the hospital. In securing smears extreme care should be taken to observe rigid antiseptic precautions. (3) That observation wards be provided. (4) That individual utensils be provided. (5) That single service diapers be used, at least for girls, or that diapers be sterilized in an autoclave at 15 pounds pressure for five minutes. (6) That nurses be required to make daily inspection of the vulva of each child at the time of bathing, and report immediately the slightest suggestion of a discharge. Other recommendations governing the detail of hospital routine and the prolonged observation of cases were adopted.

Certain Phases of the Vulvovaginitis Problem.— Dr. B. K. RACHFORD spoke on this subject, emphasizing and enlarging upon the points brought out in the recommendations and discussing specially the attitude of the laity toward this form of infection. He said that at present the very name "vaginitis" struck terror to the average individual and carried with it a stigma of disgrace that was to be deplored. He urged that efforts be made to lead the laity to a recognition of the fact that vaginitis in the child and in the adult were different. A proper attitude in respect to this form of infection would be an important step towards its prevention and elimination.

Provocative and Prophylactic Vaccination in the Vaginitis of Infants.— Dr. ALFRED F. HESS of New York read this paper. He said that in the institution with which he was connected their efforts were directed toward preventing the admission of infected infants, in attempting in many different ways to avoid the spread of the infection, in diagnosing the cases at the very earliest possible moment, and, finally, in resorting to every means to effect a cure. There was no doubt that vaginitis might be due to other organisms than the gonococcus. Tests had been carried out by Dr. Edwin Langrock that showed that pus cells might be found in the smears taken from infants during the first 48 hours of life and that these must not be regarded as pathological but as a probable reaction of the external tissues to the inevitable invasion of bacteria. They had found that the fundamental cause of vaginitis must be considered to be the latent carrier, some healthy infant who harbored the gonococcus. During the past five years autopsies had been performed on four infants who had vaginitis while in the institution. They all showed the same pathological condition. Macroscopically the vagina appeared negative, as did the body of the uterus and appendages. The only abnormal condition was redness of the tip of the cervix, so that we must regard the average gonococcus infection as a cervitis rather than a vaginitis. The degree of vaginitis in children who applied for admission to the institution was about 50 per cent., indicating that the disease was not particularly associated with child-caring institutions. In order to overcome the danger of the latent carrier they had, during the past year, administered three injections of gonococcus vaccine to infants soon after they were admitted to the institution. The object of these injections was provocative, to see if they would bring to light a latent infection. The dosage was entirely empirical. At the present time they were giving 100, 200 and 400 millions. Usually two injections were sufficient to bring about a reaction. During the past year these provocative injections had led to the discovery of eight new cases during the first week or two after their admission to the institution. The vaccine was found to be valuable, not only for diagnostic measures, but to a certain extent for prophylaxis. It had been used in about 100 infants and by it they had been able to change the entire nature of the vaginitis in their institution and as a result they had a nonclinical type of the disease. There was not only an acquired susceptibility to gonococcus infection, but also a natural susceptibility and a well defined natural immunity. This immunity was rare and in many instances not absolute.

Some Early Symptoms Suggestive of Protein Sensitization in Infancy. — Dr. B. RAYMOND HOOBLER of Detroit presented this communication. After referring to the work of Dr. Talbot in respect to the action of foreign proteins in causing asthma and that of Dr. Schloss in respect to their relation to eczema and gastrointestinal disturbances, said that he had made observations and had collected considerable data concerning the early symptoms of protein sensitization in infancy. He also reported on the symptoms that were observed in guinea pigs sensitized to foreign proteins. In these the first symptom of protein sensitization was peripheral irritation; the reward was characterized by convulsions, and the animal either died in this stage, or immediately following a convulsion. When this second stage was not reached the animals usually made a complete recovery. These symptoms were quite similar to those seen in a human being sensitized to a foreign protein; this sensitization was characterized by the appearance of a rash, urticarial or erythematous, vomiting, great muscular weakness, and in rare instances speedy death. Patients having this condition might be classed in three groups according to the intensity of the symptoms, whether mild, moderate, or severe. The degree of intensity of the symptoms depended upon the quantity and frequency with which the foreign protein was injected. There may also be a family predisposition to some form of sensitization in the father, mother, or grandparents to the protein of egg, milk, oatmeal, fish, or some other food. It was important to know whether one was dealing with a patient with such a hereditary tendency. The skin manifestations which apeared first might be the form of the mildest erythema, or an intense urticaria, or there might be single wheals like an insect bite, or again it might be of the miliary type, the class of eruptions formerly classified as intestinal rashes. There might also be vasomotor disturbances, as sneezing snuffles, or dry cough, as in infants who had many colds and never showed any pathological lesion; these were frequently showing the first symptoms of anaphylaxis. Other symptoms were asthmatic attacks which appeared and then disappeared as suddenly as they had come, recurrent attacks of acute indigestion, fretfulness, irritability, and sleepness. Fortunately all these symptoms did not usually appear in one child. Sometimes one and sometimes another of these symptoms would be premonitory. At times the symptoms persisted throughout life and sometimes they disappeared later in life. Certain nutritional disorders of a biological character might be of this nature. Many of these symptoms were symptoms of other diseases, but when one got this group of symptoms and they recurred from time to time they should

be suggestive of anaphylaxis and it was important to have this condition recognized early.

Dr. Oscar M. Schloss of New York said that it was only rational if they assumed that the acute explosive attacks were of anaphylactic origin to believe that there were milder types which bore a definite relation to them but were not so marked. Many of the milder disturbances might suggest sensitization to a food protein, yet there was no definite evidence that such was the case. Many more experiments would have to be made before one could make definite statements on this phase of the subject. The question of heredity in connection with protein sensitization was of great interest. In the majority of cases reported and in those he had seen the parents or others in the family had shown some allied condition. Usually the treatment of desensitization which he had described gave good results.

Dr. Fritz B. Talbot of Boston said it should be remembered, in discussing this problem, that the condition of anaphylaxis which gave symptoms was a relatively rare one. In looking over hospital records he had found that there were relatively few cases of asthma, but a considerable number of skin cases that might be due to anaphylactic action. He had been able to find few cases of erythema due to anaphylaxis, but he believed that all urticarias were due to some form of anaphylaxis. Miliary rashes he was unable to connect with any anaphylactic phenomena. Rough skin might be due to anaphylaxis; it had seemed to have such a connection in one case and also with deficiency of thyroid secretion. Some of these cases gave a definite skin test, but they did not always get well when one took out the food that gave the skin reaction. The respiratory symptoms, common colds and snuffles, Dr. Talbot said, he would put down to adenoids. Other symptoms which were mentioned in connection with the respiratory system he would diagnose as bronchitis or croup. Some symptoms of indigestion were of anaphylactic origin, but he thought this was one of the last things in connection with anaphylaxis that they would be able to prove. Several of his patients had volunteered the information that when they took a protein to which they were sensitized they had the sensation that it stayed in the throats, and some said that it gave them a shivering sensation.

Calcium Metaholism in a Case of Hemophilia.—Dr. D. Cowie and C. H. Laws of Ann Arbor presented this report. They stated that the subject upon whom the observations were made was a hemophiliac and gave a family history of bleeding. They found that by administering large doses of calcium the calcium content of the blood could be raised but as soon as the calcium was discontinued it immediately dropped. The conclusions they drew from this work were that in this hemophiliac the calcium content of the blood was below normal: that by feeding calcium the amount of calcium in the blood could be increased appreciably, and that during this time the coagulation time was lengthened.

The Calcium Content of the Blood in Rachitis and Tetany.—Drs. John Howland and McKim W. Marriott presented the results of this investigation. They reviewed the theories that had been advanced in respect to rickets and calcium metabolism, and said that there had been no studies made to show whether calcium was present in sufficient amounts in the blood of rachitic patients. They had advised a method by which they could determine the amount of calcium in one-half c.c. of blood serum, and had determined the calcium content in the blood of 11 cases of rickets and a number of controls. They had found in the greatest number of instances a value between 10 and 11 mg. per 100 c.c. of blood serum. In those having rickets there was in some instances a reduction of calcium, but they never found less than 9 mg., and often ten or nearly 11, so they thought that they could say that rickets did not depend upon an insufficiency of calcium, but primarily on some condition in the bone. It had also seemed that some calcium disturbance was related to the onset of tetany. They therefore determined the amount of calcium in the blood of seven infants with tetany by means of accurate technique and all showed a marked reduction in the calcium content of the blood. They found that in general the figures ran between 6 and 7 mg. of calcium per 100 c.c. of serum, though in one instance it was as low as 5 mg. They also made the determination in two children with no active symptoms of tetany, but who gave an electric reaction, and in one of these there was a moderate reduction of the calcium and in the other none. When the child lost the evidences of tetanus the calcium content of the serum became normal. The findings in children with convulsions were almost the same as in dogs that developed tetany after thyroidectomy, in that the calcium content was somewhere between five and seven mg. per 100 c.c. of serum. It seemed that the parathyroid exerted a distinct effect on the calcium in the blood.

Dr. L. Emmett Holt said the findings of Dr. Howland were very well borne out by the effect of magnesium sulphate administered hypodermically in tetany. He had given calcium chloride by the mouth in large doses, but the results were slow in manifesting themselves. During the last two years he had been administering magnesium sulphate hypodermically and the results manifested themselves in from fifteen to twenty minutes. One did not need to repeat this oftener than once in twenty-four hours. One should use the anhydrous salt which was twice as strong as Epsom salts.

Early Morning Toxic Vomiting in Children.—Dr. Thomas S. Southworth of New York read this paper in which he directed attention to the vomiting of children which not infrequently occurred in the early morning either before or soon after the first feeding. This he believed was of toxic origin since the vomitus after the long night period contained no food residue unless a morning feeding had been given. It was sharply distinguished from the vomiting of undigested and fermenting food from failure of gastric digestion, which usually occurred later in the day. The cases, one of which was related as typical, had neither the characteristic histories nor clinical symptoms and course of recurrent vomiting, which was another toxic type. In the recurrent type the toxemia was probably of gradual and cumulative evolution, brought to a head by constipation or some unusual factor. Elimination was slow and vomiting prolonged. Fever was not constant. In the type under consideration with early morning vomiting fever was a usual accompaniment, often rising sharply, and there was an acute putrefactive process in the intestine with absorption and attempted re-elimination by the gastric mucous membrane. It was assumed that this toxic material accumulated in the stomach during the hours of slumber when reflexes were more or less deadened and asserted its presence in vomiting after awakening. Purgation resulted in foul stools often containing mucus. After the stomach was emptied by one or two acts of emesis at short intervals there was not the same tendency to recur which obtained in the recurrent type. The extreme caution in the resumption of feeding often displayed after attacks of recurrent vomiting frequently led to under-nutrition in children whose attacks occurred at rather short intervals. A slightly greater care was demanded in the acute toxic type of intestinal origin, especially in the summer months because of the intestinal condition, but with care and reasonable feeding might be promptly inaugurated. The author believed early morning vomiting without food residue from the previous day to be a sign of value as indicating an acute toxemia arising in the intestinal tract.

Dr. T. DeWitt Sherman asked Dr. Southworth if he had had gastric analyses made of the vomited material at any time and whether it showed achylia of hyperchlorhydria and whether there might be a neurotic element involved.

Dr. Fritz B. Talbot asked Dr. Southworth if he had tested for acetone in the early morning urine. He said he had quite a number of instances of this kind and invariably found acetone.

Dr. Isaac Abt of Chicago said that the vomiting might be the effect of something outside the gastrointestinal tract. The chronic alcoholic vomited because he had a nasal pharyngitis. It was possible that a pharyngitis might have had something to do with the production of the vomiting in several of these cases.

Dr. Southworth said he had made no such examinations and it was probable that some of these children might have had hyperchlorhydria. If there was a definite odor of acetone an examination of the urine was made. As to Dr. Abt's question, if he had seen these cases there would have been no question in his mind that they were as stated. A child coughed a great deal because of the presence of mucus in the pharynx, but the type of case referred to had no cough which could have been the cause of the early morning vomiting.

A Study of the Etiology of Chorea.—Drs. John Lovett Morse and Cleaveland Floyd of Boston presented this communication which was read by Dr. Morse. He said this study was undertaken primarily to determine, if possible, the parts which syphilis and bacterial infection played in the etiology of chorea. A

review of the literature seemed to show that there was very little evidence in favor of the syphilitic origin of chorea and much against it. In their investigation of 26 cases of chorea there was nothing whatever in the history of 21, or 81 per cent., of these cases to suggest syphilis. In the others there was a history of miscarriages. The blood of three of the children in whose families there was a history of miscarriages gave a negative Wassermann test. None of the children showed any of the stigmata of syphilis. Of the 25 children in this series, 21, or 84 per cent., gave a positive skin reaction to tuberculin, yet it would be absurd to assume that tuberculosis was the cause of chorea in these 21 children. The conclusion, therefore, seemed justifiable that syphilis seldom, if ever, played an active part in the etiology of chorea. This series of cases confirmed the general belief as to the frequency of the association of chorea with rheumatism and endocarditis. Seven, or 37 per cent., had had rheumatism in the past or in connection with the chorea; six of them had acute endocarditis, and six chronic valvular lesions, a total of 12, or 46 per cent. The tonsils were normal in but 11 cases, or 42 per cent., and had been removed on account of disease in four others. The teeth were normal in but seven of these patients; pyorrhea was present in two, and definite pus pockets were found in three others when the teeth were extracted. A review of the literature showed that the results thus far obtained from blood cultures were inconsistent and inconclusive. Dr. Morse said that during the past year he and his associate had made a study of these 26 cases of chorea in the acute stage of the disease with a view to determining the presence of an infecting agent in the blood stream and cerebrospinal fluid, the frequency with which it could be obtained, and its cultural characteristics. In every instance the cultures as well as the smears from the cerebrospinal fluid were negative. Blood cultures were negative in all but five instances. In one case a small bacillus, diphtheroid in type, appeared. This was a Gram negative organism and was not pathogenic for rabbits. Diplococci were found in one case, but no organisms were cultivated. In both of these instances the tonsils were enlarged and the teeth carious. In another case positive blood cultures were obtained after ten days of incubation and this patient had endocarditis and had had several attacks of rheumatism. Autopsy in this case showed a general septicemia and cultures from the heart's blood and the knee joints gave a good growth of streptococci. The fact that the organism taken from this patient caused lesions in the brain and meninges of rabbits similar to those found in the brain and meninges of this patient at autopsy suggested that it was also the cause of the chorea in this child. The absence of organisms in these cases might be explained by the fact that most of them were mild or only moderately severe in type. It might also be possible that the failure to detect the organisms more often in the blood or spinal fluid might have been due to the fact that they were only temporarily present in the blood stream and tended to locate themselves in the meninges, endocardium, or joints. While there was much that pointed to a microorganism or group of microorganisms as the cause of chorea the bacterial origin of chorea was not as yet proven.

The Effect of Subcutaneous Injections of Magnesium Sulphate in Chorea.—Dr. HENRY HEIMAN of New York, presented a brief report on several cases of chorea treated by subcutaneous injections of magnesium sulphate. He said the effect of this agent seemed to be entirely negative and that they could not hope to give any relief in chorea by the administration of magnesium sulphate subcutaneously.

The Prognosis and Treatment of Banti's Disease in Children.—Dr. EDWIN E. GRAHAM of Philadelphia read this paper. He stated that the juvenile form of this disease tended to run a more acute course than the adult form. If not treated or if treated only medicinally it was almost invariably fatal. Under surgical treatment the prognosis was rather more favorable than otherwise, the outlook depending upon the duration of the disease at the time the spleen was removed. If done early splenectomy was attended with slight mortality, and in uncomplicated cases a cure might be expected; but when the disease was complicated by other affections of chronic infectious nature, the value of the operation was questionable. Splenectomy was even more advantageous in children than in adults. After the removal of the spleen in most cases the blood picture more or less approached normal, but in a few cases it might vary greatly, so that five years might elapse before the count became normal. When Banti's syndrome was well established the prognosis was most unfavorable even though splenectomy was performed. If an abundance of iron was supplied to the system after the removal of the spleen which was the organ in which metabolism took place, polycythemia would take place in many cases, and an increase in red cells was always noted at varying intervals after operation; therefore in splenic anemia iron was undoubtedly indicated both theoretically and practically. Splenectomy was both useless and dangerous in cases in which the hemoglobin was below 30 per cent., and the red cells below 2,000,000. The operation should as a rule be attempted only when there was no edema, no parenchymatous nephritis, and no serious degenerative change in the liver, and while the patient was still able to go about. In severe cases blood transfusion done shortly before the operation seemed to increase the ability of the child to withstand the shock of the operation. Dr. Graham reported in detail a case of splenectomy in a child nine years of age in which recovery ensued.

Dr. HENRY KOPLIK said he thought there might be some question whether all the cases reported as Banti's disease were really such. He cited an instance of a patient who as a boy had jaundice and an enlarged spleen. Operation was refused. The boy had grown to manhood and was now an engineer. He was now in apparently good health though he still had an enlarged spleen and liver.

Wednesday, May 10—Third Day.

Familial Icterus in the New Born.—Dr. ISAAC ABT. of Chicago made this contribution. He stated that familial icterus had nothing in common with Buhl's or Winckel's disease. There was no evidence to prove that it was a septic process. It was not present at birth, in none of the cases reported was there a history of birth injury, and it did not seem to be due to the toxemia of pregnancy. One might say that the children were in a sense defective and very soon after birth became incapacitated to carry on extrauterine life. The disease usually began on the second day of life and rapidly increased in severity. The symptoms were those described by Pfannenstiel, namely, catarrhal condition of the mucous membrane, sometimes with bloody discharge, frequent catarrhal stools, bile pigment in the urine, and meningeal irritation. The disease occurred in successive pregnancies. Occasionally several normal children would be born and then several would die in a few days after birth as the result of grave and progressive icterus. The disease bore no relation to syphilis and had nothing in common with family jaundice. Isolated instances of this condition had been reported from time to time, but the writer had encountered examples of familial icterus in the new born in two families. The first occurred in an Italian family in which there was nothing in the history of the parents or grandparents in any way connected with the condition in this infant. The mother had borne five children, two of whom were living and three dead. The two eldest children had always been well; the third baby seemed strong and robust at birth, developed jaundice on the second day and died on the third day. The history of the fourth and of the fifth, the case he had observed, was the same. The second case occurred in a Russian family. The mother, 23 years of age, had borne six children. The first child had chronic nephritis and was 11 years of age. The second child was living and well. The third pregnancy resulted in miscarriage. The fourth child became jaundiced on the second day, was seized with convulsions, had frequent stools, became worse, and died on the third day. The fifth child gave a similar history. The sixth child became jaundiced on the second day, its condition grave on the third day, but on the fifth day an improvement was noted, the jaundice gradually disappeared, and the baby was now a year old and well.

Dr. WILDER TILESTON of New Haven called attention to the fact that in these cases there was a yellow icterus staining of the base of the brain which was never seen in jaundice and which might be correlated with the nervous symptoms.

Dr. T. DEWITT SHERMAN of Buffalo said that poisons had been mentioned as a cause of jaundice and the question had occurred to him whether jaundice and allied conditions might be due to the poison of chloroform administered to the mother at the time of labor, since they knew that chloroform produced hyaline and fatty degeneration and this effect was concentrated on the liver.

Measles, Pertussis, and Pneumonia.—Drs. P. J. EATON and E. B. WOODS of Pittsburgh reported a group of cases which appeared simultaneously in one family chiefly because it showed the peculiar mix-up of infectious disease that might be possible. Two children in a family were about half way through whooping cough when a third child came down with measles, then whooping cough, followed by a chest deformity, which gradually disappeared. One of the two children having whooping cough contracted measles, which was followed by pneumonia, while the other did not; the latter child was watched very closely. The measles cases were treated by cool, fresh air and vaccines. Dr. Eaton stated that it was his custom to administer vaccines to children who were exposed to measles.

Scarlet Fever and Measles Occurring Simultaneously.—Dr. D. J. MILTON MILLER of Atlantic City presented this paper. He said he reported these cases not because of their great rarity but because they were interesting. There was an impression that if a child was suffering with one infectious disease he was immune to others, but this was a mistake. Patients suffering with one infectious disease seemed to be more susceptible to other infections. This seemed to be especially true of measles, pertussis, and scarlet fever. It was quite usual when one of these diseases occurred to have it followed at short intervals by another or they might be concurrent from the outset. In scarlet fever and measles the diagnosis was very difficult. The case presented had the usual symptoms of measles. On the tenth day a characteristic scarlatinal desquamation was observed, and a complicating otitis media followed. Three sisters of the patient contracted measles but not scarlet fever. One of these children who was not isolated did not contract scarlet fever. One of the sisters who never came in contact with the patient contracted measles.

Dr. MATTHIAS NICOLL of New York emphasized the fact that the character of the desquamation in scarlet fever was not always typical. He had seen sheet desquamation in measles, though it was rare.

Dr. MILLER said he felt convinced that his first case was one of scarlet fever, as the peculiar eruption at the finger nails was present and he had never seen this in any other disease than scarlet fever; his diagnosis rested to a great extent on that.

Observations on Measles.—Dr. CHARLES HERRMAN of New York presented this communication. He stated that the deaths reported as due to measles gave an inadequate idea of the real number caused by this disease. A large number died from complicating bronchopneumonia, especially between the ages of one and two years. This was suggested by the parallelism between the curve of morbidity from measles and the curve of mortality from bronchopneumonia between one and two years of age. In a series of 300 secondary cases of measles which he had observed, the fever appeared on the tenth or eleventh day from the time of infection in 56 per cent.; catarrhal manifestations on the eleventh or twelfth day in 60 per cent.; the tonsillar spots on the ninth to the thirteenth day; the Koplik spots on the eleventh or twelfth day in 54 per cent.; the eruption on the twelfth to the fourteenth day in 67 per cent. In 7.2 per cent. the catarrh was present on or before the tenth day; the Koplik spots in 12.8, and the tonsillar spots in 34 per cent. In 4 per cent. of the cases in which the tonsillar spots were present as early as the seventh day and in a few cases the tonsillar spots were present in patients who did not show the Koplik spots. The presence of the tonsillar spots would be found valuable in schools, hospitals, and asylums, in detecting and isolating the patients early. Infants under two months of age were absolutely immune. At eight months this immunity had gradually disappeared. This gradual disappearance was shown by a longer period of incubation. In infants between five and eight months the disease was usually milder. This was also shown by the fact that only 41 per cent. of these lost weight, whereas of those between eight months and two years 76 per cent. showed such a loss. The immunity was probably conveyed through the placental circulation; only those infants whose mothers had the disease seemed to acquire it. Infants between three and five months who had come into intimate contact with measles and did not contract it, sometimes were not infected when exposed later in life.

Dr. HENRY KOPLIK said that five days before the appearance of the eruption in measles a febrile movement and the Koplik phenomenon might be observed. There was absolutely no other reaction during this time except the slight fever.

Dr. S. MCC. HAMILL of Philadelphia asked Dr. Herrman if he implied that it would be a good thing to expose children under five months of age to measles.

Dr. HERRMAN, in closing, said he had not said that it would be a good thing to expose children under five months of age to measles because one could not be absolutely sure that they would not contract the disease. He would not like to put himself on record as advising exposure of a child to an infectious disease. What he had brought out in his paper would explain why children from five to eight months of age had the disease in a mild form.

The Energy Metabolism of a Cretin.—Dr. FRITZ B. TALBOT of Boston presented this study. He said that a typical cretin, three years and 8 months of age, was studied in the respiratory chamber devised by Benedict in the Laboratory of the Carnegie Institute at Washington. They found his basal metabolism per kilo body weight was 40½ calories per square meter body surface, 898 calories per 24 hours (Lissauer). In the absence of normal data in children of the same age, this metabolism was compared with that of a normal eight months' baby and a normal ten months' baby. It was found that the metabolism of the cretin was decidedly lower than that of the two normal babies. Unfortunately results after treatment with thyroid had not been sufficiently accurate to use. These results were consistent with those of Magnus Levy and the more recent work of Dubois in Lusk's Laboratory. The practical application of these findings was that the cretin required less food than children with sufficient thyroid activity and after treatment with thyroid extract would require more food than before treatment.

The Bacteriology of the Urine in Healthy Children and Those Suffering from Extraurinary Infection.—Dr. HENRY F. HELMHOLTZ of Chicago reviewed the various theories as to the mode of infection in pyelitis in children and said he thought a study of the bacteriology of the normal urine and urethra might throw some light on this problem. With this object in view he had examined catheterized specimens taken from thirty infants and from thirty-one girls over two years of age. The urine was collected by a very careful technique. It was found that in 119 specimens taken from 61 different individuals, 61 were sterile, and 58 contained bacteria. Of those from 24 normal infants 13 were sterile and 11 contained bacteria. In specimens from girls over two years of age 35 were sterile and 27 contained organisms. The number of bacteria found in the first series was considerably larger than in the second. This might be explained by the fact that in the older children one could cleanse the urethral orifice much easier and could introduce the catheter directly into the urethra. The bacterial flora was practically the same in both series, Gram positive staphylococci and pseudodiphtheroid organisms predominating; the former were present in practically every case in which any organisms were found. The writer concluded that it might be assumed on the evidence given that organisms of the colon group were not normal inhabitants of the female urethra and that in extra-urinary infections occurring in the first two years of life the colon bacilli were frequently found in the urethra, that was in about one-third of the cases. In girls over two years of age the urethra was almost free from organisms and entirely free from organisms of the colon group.

Oxycephaly in Two Brothers.—Dr. W. W. BUTTERWORTH of New Orleans reviewed the literature of this subject and said the classical symptoms of oxycephaly were exophthalmos, pain, and some disturbance of vision. It was a rare occurrence to find this condition in two brothers with a history of a similar condition in the grandfather. These children were not mentally deficient. The condition had been variously attributed to ossification of the sutures, defective bone development, and a hydrocephalic condition in infancy. The *x*-ray pictures showed a mottling of the inner plate of the cranium and *x*-ray pictures of the other bones showed that enlargement of the condyles of the large bones was not unusual and that there was some enlargement of the bones of the face.

Meningitis in the New Born and in Infants under Three Months of Age.—Dr. HENRY KOPLIK of New York presented this communication. He said that meningitis in the new born might be secondary to general sepsis or it might occur as a primary infection. The symptomatology in the primary condition was very obscure. The signs by which meningitis was recognized in older children were not applicable to these babies.

There was no rigidity, no bulging, no Babinski, and no condition of muscle clonus, so that it was not to be wondered at that the diagnosis was difficult to make. He had sought for some characteristic symptoms. He had found that the convulsions might be simple or there might be only slight twitchings of the extremities. Again, there might be only one convulsion with very high fever 105° F. or over, and then this might remit or subside. After the disease had lasted for a week or ten days the temperature came to a lower level and might run along at about 100° F. or slightly above. Bulging of the fontanel was not present; in some cases there seemed to be a depression. Macewen's sign was very difficult to determine in new born babies. Some gave the signs of fluid in the head and some did not. It was only later in the disease after a week or ten days that one could get the signs of fluctuation, and the increase in the quantity of fluid could be detected by the bulging and by the tympanitic note over the temple. The trauma incident to difficult labors made the diagnosis more difficult in some instances. In some infants the disease was very severe and in some the symptoms were so mild that even the mother did not notice them until the child was two and one-half to three months old. The results of lumbar puncture in these cases was very interesting. In a series of twelve cases the streptococcus was isolated four times, the pneumococcus three times and the meningococcus three times; two were secondary cases. One case showed very distinctly that the meningitis was secondary to arthritis. In the secondary cases the streptococcus was found in the blood. The other case which he had observed began with a pyelitis and later developed a colimeningitis as a secondary infection. The fate of these babies was disheartening; they were all fatal sooner or later. Only one out of the twelve was still alive and that one had a marked hydrocephalus. Newborn babies did not bear lumbar puncture well. In discussing the modes by which infection might take place, Dr. Koplik suggested that during resuscitation by the suction method infection might be conveyed if the attendant was a meningitis carrier, and it might also be the result of trauma or of putting the fingers in the infant's mouth.

The Use of Salt Solution by the Bowel in Infants and Children.—Dr. Edwin E. Graham of Philadelphia presented this paper in which he said that his experience with the Murphy method of injecting saline solution by slow proctoclysis in certain conditions in children had led him to believe that it was of much more value to the pediatrist than most of them were aware of. In the acute infectious diseases toxemia might be greatly influenced by the employment of the Murphy drip. It was also of value in uremia and suppression of urine and generally speaking for toxemia from any cause, whether it was autointoxication, mineral poisoning, or septicemia. If nephritis with edema was present the administration of salt solution by this method was unwise, although in a few such cases it had apparently been employed with success. Dr. Graham said he had been greatly impressed by the results of the Murphy drip in profuse diarrhea due to intestinal infection. In employing this method there were several points to be observed: The catheter must be introduced 4 or 5 inches into the bowel; there must be a good return flow, and the water must be kept at a temperature of about 110° F. The water should have a drop of about 12 inches. It was a good plan to allow it to flow for an hour and then allow the patient a rest of one hour. If slight edema made its appearance the treatment was to be discontinued. The solution should be carefully prepared; to say a teaspoon of sodium chloride to a pint of water was exceedingly inaccurate.

A Case of Disseminated Sclerosis.—Drs. George N. Acker and Joseph S. Wall reported this case. Dr. Acker stated that the patient was a colored child 4½ years of age, who came to the out-patient department of the Children's Hospital on March 2, 1916, complaining of "nervousness." The family history was negative. The child's trouble had come on gradually and she had grown progressively worse. The chief symptoms presented were shaking of the body, nystagmus, exaggeration of all the reflexes, rapidity of pulse, but not enlargement of the heart. Ten days later her symptoms were aggravated and her mental condition seemed dulled. The drinking test gave rise to a typical volitional tremor. There were marked elbow and wrist jerks and ankle clonus was present in both extremities. The heat and cold sense were apparently normal except in the right thigh where there was some dissociation of the senses. The writers were of the opinion that the case fell into the category of disseminated sclerosis.

Dr. Joseph S. Wall of Washington reported on the present condition of the child which, he said, was, on the whole, changed but little from that recorded in the paper.

The Danger to Hospital Efficiency from Diphtheria Carriers.—Drs. Samuel S. Adams and Frank Leech of Washington, D. C., made this contribution. They emphasized the point that there must be team work on the part of all connected with the hospital from the highest authority to the humblest employee. Among the numerous details that were requisite for the proper administration of a hospital it was important that every hospital have a well-trained medical superintendent who should have exclusive control over all matters connected with the hospital. The members of the medical staff should be medical men who had been promoted from dispensary work. Provision should be made for follow-up work not only for the hospital but for the out-patient department. Efficiency experts should be engaged from time to time to check up the work and criticise the same, from the president of the Board of Directors to the orderly. The writers then described a diphtheria epidemic in the hospital with which they were connected which had greatly hampered the work of the hospital for a number of weeks. The occurrence of two cases of diphtheria led to a culture of every individual in the house with the result that 51 positive cultures were found out of a total of 100, including employees, nurses, and internes. The hospital wards were closed for a period of three weeks to the reception of new patients. At present they had reduced the number of positive cultures to seventeen. A search for the source of infection seemed to point to a nurse in the baby ward who had suffered from sore throat. There were twelve babies in this ward and eight gave positive cultures. To prevent the occurrence of such outbreaks they felt convinced that all institutions for the care of sick children should be provided with a suitable detention ward for the detention of all new admissions. Cases when admitted should have nose and throat cultures taken and be placed in the detention ward for five days. If it was impossible for financial reasons to provide a detention ward, cubicles should be provided in each ward and proper nursing technique carried out to prevent the dissemination of minor contagions. Illness in internes and nurses should be immediately attended to. Visitors to ward patients should be restricted to adults only, and such visitors admitted as infrequently as possible. Tests of the virulence of diphtheria carriers should be made, thus relieving ourselves at once of a large number of cases which it would be otherwise necessary to isolate.

The Schick Reaction in Infants.—Drs. Henry L. K. Shaw and William E. Youland of Albany presented this communication. They stated that there was no question of the accuracy of this test in detecting the individual susceptibility and immunity to diphtheria. A review of the results of the Schick test as reported by various observers in cases under one year of age, showed a variation of from 0 to 40 per cent., and from one to two years of age the variation was from 15 to 65 per cent. The writers had made an investigation among ninety-five infants under two years of age in two infants' institutions and two hospitals in Albany. In making the tests they used the standard diphtheria toxin diluted so that 1 c.c. contained one-fifth the M. I. D. and 0.1 c.c. of this diluent was used in making the test. The procedure of Park and Zingher of heating one-half of the diluted toxin at 70° C. for three minutes was used for the purpose of control. The reactions were read daily and the final interpretation made on the fourth day. In practically no case did a typical pseudo reaction occur. In some cases the reaction did not appear until the third day, though it appeared more frequently on the second day. In 66 children under one year of age they found 47 per cent. positive, while of 29 children between one and two years of age 58.6 per cent. were positive. These results were remarkably similar to those of Park and Zingher. From their experience with this group of cases it would seem that when virulent diphtheria bacilli were found in infants having no antitoxin in their tissues, a careful examination for diphtheritic rhinitis should be made, as they had five cases in which, without such examination, it would have been overlooked.

State Medical Licensing Boards.

STATE BOARD OF EXAMINATION QUESTIONS.

Ohio State Board of Medical Examiners.

June 6, 7, 8 and 9, 1916.

(*Concluded from page 398.*)

PRACTICE.

1. Describe the symptom complex of uremia; tell how you might suspect it to be impending in a given case, and what treatment you would employ in an effort to avert it.

2. In what diseases should one be on the lookout for acute endocarditis, and how would you recognize its occurrence?

3. Give symptoms of cancer of the liver involving the neighborhood of the hepatic duct.

4. Given a case of a man of sixty-five of alcoholic history, with edematous ankles, dyspnea, and cough with occasional bloody expectoration, albuminuria, and blood pressure of 150 (sys.); what would be your presumptive diagnosis?

(*b*) Trace the prognosis of the case from the primary condition.

5. In an instance of alleged hematemesis, give other possible sources of the blood, and tell how you would recognize the origin in a given case.

6. Describe your treatment of a case of pulmonary tuberculosis, moderately advanced, involving chiefly one side, with a temperature of 101° Fahrenheit, and subject to occasional hemorrhage.

7. Give symptoms and treatment of a case of influenzal pneumonia.

8. Give symptoms of acute myelitis, differentiating it from multiple neuritis.

9. Mention some indications of cerebral syphilis. How would you make a positive diagnosis? Briefly outline the treatment.

10. How would you treat a case of acute articular rheumatism?

DERMATOLOGY, SYPHILOLOGY, AND DISEASES OF EYE, EAR, NOSE, AND THROAT.

1. Describe psoriasis. Give treatment.

2. Of what disease is the occurrence of pruritus ani a frequent sign?

3. Upon what evidence would you base a belief that a patient is cured of gonorrhea?

4. Describe signs and symptoms of congenital syphilis.

5. Outline an approved treatment of syphilis.

6. What are the dangers of acute suppurative inflammation of the middle ear?

7. Describe trachoma. Give treatment.

8. Describe tuberculous laryngitis.

9. Give treatment of acute suppurative inflammation of frontal sinus.

10. Give treatment of nasal polypi.

OBSTETRICS.

1. When would you be justified in inducing premature labor?

2. How would you diagnose the existence of pregnancy?

3. What are the symptoms of fetal death?

4. State the indications and contraindications for the use of the curette and describe the technique of this operation.

5. Name the stages of labor and describe the management of the third stage in detail.

SURGERY.

1. Shock: (*a*) Cause; (*b*) Symptoms; (*c*) Outline treatment.

2. Acute Suppurative Appendicitis. (*a*) Diagnosis: (1) Subjective and objective symptoms; (2) Differentiate between this and similar abdominal disorders; (3) Preliminary treatment. (*b*) Operation: (1) Surgical technique; (2) After treatment; (3) Prognosis.

3. Colles' Fracture: (*a*) Diagnosis; (*b*) Pathology; (*c*) Treatment.

4. Hip-Joint Disease: (*a*) Diagnosis; (*b*) Treatment—surgical, mechanical; (*c*) Prognosis.

5. Gunshot Wounds: (*a*) Give rule regarding probing; (*b*) Give rule regarding immediate operation; (*c*) In a gunshot wound of the knee what would be your course of pursuance?

ANSWERS.

PRACTICE.

1. *Symptoms of uremia.*—Headache, insomnia, convulsions, vomiting, delirium, dyspnea, amaurosis, and coma. Uremia may be suspected from the presence of nephritis, a urinous odor of the breath, scanty urine, and increased arterial tension.

The patient should be put to bed; croton oil (1 minim) may be administered; vensection and dry cupping over the kidneys may be tried; diaphoretics are useful.

2. *Endocarditis* is apt to occur during or following rheumatism and scarlet fever. The signs and symptoms may be negative; but there is generally some alteration in the character of the heart sounds, and dilatation of the heart may be present; the pulse rate is often increased. The sounds heard depend upon the valve affected, and since the mitral valve is the one most commonly involved there is apt to be a systolic murmur heard best at the apex and transmitted to the left axilla.

3. *Symptoms of cancer of liver.*—Pain, tenderness, and a sense of weight in the hepatic region; emaciation and weakness; cachexia; jaundice, vomiting, and fever.

4. The case is one of cardiac decompensation, following endocarditis (which may have been due to rheumatism, scarlet fever, or some other infection). The prognosis of endocarditis is good so long as compensation is maintained; but is unfavorable when compensation is ruptured.

5. In a case of alleged hematemesis other possible sources of the blood are: The blood may have been swallowed (as in epistaxis, after tonsillectomy, pulmonary hemorrhage). The main question is to differentiate between *hematemesis and hemoptysis:*

Hematemesis.	Hemoptysis.
1. Previous history of gastric, hepatic, or splenic disease.	1. Previous history of pulmonary troubles.
2. Blood is vomited.	2. Blood is coughed up.
3. Blood is dark colored and not frothy.	3. Blood is frothy and bright red.
4. Blood may be mixed with food.	4. Blood may be mixed with sputa.
5. Giddiness or faintness usually precedes vomiting.	5. Sensation of tickling in the throat usually precedes.
6. Nausea and weight in epigastrium.	6. Dyspnea and pains in the chest.
7. Often followed by melena (black, tarry stools).	7. Is not usually succeeded by melena.

(Hughes' *Practice of Medicine.*)

6. *Treatment of pulmonary tuberculosis:*—"By day the consumptive should be, short of actual fatigue, as much as possible in the open, and at night the windows should be widely open top and bottom. Where there is fever he must keep to bed; but when possible the bed should be outside, and where that is not possible the windows must remain open in presence of fever or any other acute symptom. In ordinary circumstances he should sleep alone. A stuffy bedroom with several people in it means rapid deterioration for the patient, and infection for the rest. *Sanatorium treatment* is not yet possible for all, nor, except in incipient cases, and in the rich, can it be continued long enough for cure; but it reduces the disease to a quiescent stage, and trains the patient in the habits he must afterwards continue. Sea voyages undoubtedly do good in many cases of early phthisis, the comparative sterility of the air contributing to the result; but no consumptive who is not a good sailor should be sent on such a voyage, nor any one who is unable to travel in comparative comfort, or who must travel alone. In the later stages sea voyages are contraindicated. If change of climate is decided upon, the place selected should be sunny, and should give facilities for the open-air life. Either a dry cold climate may be chosen or a warm one, according to circumstances. In the earlier stages cold dry air is best. High altitudes are, however, unsuitable for those with a tendency to hemoptysis. Adjuvants to the open-air treatment are *exercise* and *dietetic treatment.* The consumptive should wear wool or flannel next the skin, but should not be overloaded with heavy clothes. Tepid baths, followed by brisk rubbing, are of benefit, and much good is done by carefully graduated exercise, which promotes a regulated auto-inoculation. The food must be nourishing

and varied, and ample in quantity, systematic overfeeding, indeed, being advocated by many. Everything must be done to combat the very common anorexia and dyspepsia.

Medicinal Treatment is (*a*) *General.*—Creosote or guaiacol, cod-liver oil, and tonics, such as the hypophosphites and arsenic, are the principal remedies. (*b*) *Symptomatic.*—The following symptoms call for special treatment:—(1) The *cough.*—As this is a persistent and constant feature of the disease, avoid rushing at once to cough mixtures. A common exciting cause of the nightly cough is the changing from a warm room to a cold bedroom; or again, tickling of the fauces by the uvula. A useful combination is that of morphine, spirits of chloroform, and dilute hydrocyanic acid. For laryngeal and bronchial irritation, inhalations of tincture of benzoin or creosote are of much value. (2) The *night-sweats.*—Picrotoxin, aromatic sulphuric acid, atropine, and oxide of zinc are the favorite remedies. Atropine gr. 1/100 to 1/80 in pill at night, is the most reliable. (3) The *diarrhea* is usually best controlled by mineral astringents, in combination with opium. (4) *Fever* should be treated by rest, fresh air, quinine, and cold sponging, or, if need be, the cold bath. Antipyrin, etc., may be occasionally used. *Hemoptysis* demands rest in bed, quiet, light food given cold, ice to suck, injections of morphine and atropine or inhalation of nitrite of amyl." (Wheeler and Jack's *Handbook of Medicine.*)

7. Lobar pneumonia. "*The first stage* is characterized by sudden onset with chill, a sharp pain in the side, rise of temperature, a short and sharp cough, rusty-colored, viscid sputum, and dyspnea. There may be headache, insomnia, scanty urine with diminution of urea, chlorides, phosphates, and sulphates, insomnia, and herpetic vesicles on the face, and there is always an increase in the number of leucocytes in the blood. Physical examination will reveal diminished expansion, impairment of the normal percussion note, feeble or suppressed respiratory murmur, moist or dry râles, crepitation, and sometimes a pleural friction sound.

In the second stage the dyspnea is more marked; the face is more or less livid in color; the temperature is high (104°-105° F.); and the pulse increases in rate (110-120), its tension and fullness lessening with the progress of the disease, and growing feeble and intermittent. Headache, delirium, and various other nervous symptoms may be present. Expansion is diminished and vocal fremitus is exaggerated upon the affected side. There is dullness with increased resistance over the consolidated lung, and auscultation detects bronchophony or bronchial breathing over this same area.

The third stage is ushered in by a sudden drop of temperature on or about the fifth or ninth day, followed by a natural sleep, free sweating, and relief from suffering. In this stage the subcrepitant râle (râle redux) is heard in the midst of the bronchial breathing, together with numerous moist râles. Dullness may persist for some time, but usually by the twelfth or fourteenth day the lung has returned to its normal state."

Treatment: "Consists in rest in bed, milk diet, and the administration of fractional doses of calomel followed by a saline in the early stage. The nervous symptoms and temperature may be controlled by applying ice-bags or compresses wrung out of cold water (60°-70° F.) to the chest or by the use of the warm or cold wet-pack. The heart and pulse should be sustained by the administration of alcohol, strychnine (gr. 1/60-1/20), atropine, caffeine, strophanthus, and nitroglycerin. Digitalis may also be employed. Inhalations of oxygen afford temporary relief when the dyspnea and cyanosis are extreme. In young, vigorous, and plethoric adults, with hyperpyrexia and a high-tension pulse, bleeding may be beneficial in the first 48 hours. Convalescence should be guarded, and tonics, stimulants, etc., will be found very useful in this period of the disease." (*Pocket Cyclopedia.*)

8. *Acute myelitis* is generally of rapid onset, the feet and legs become heavy and numb, twitching and convulsions may occur, the flexors are more affected than the extensors, walking is difficult, paraplegia develops, there is usually some fever, there may be girdle sensation at the level of the lesions, anesthesia of bladder and rectum are common, the reflexes will be absent if the lesion extends completely across the cord, priapism is common.

In *multiple neuritis* the onset is slower, the sphincters are rarely involved, the sensory disturbances are more severe, the extensors are more involved than the flexors, atrophy of the affected muscles rapidly supervenes, the mental condition is frequently affected.

9. *Indications of cerebral syphilis:* Headache, usually worse at night; insomnia; vertigo; hemiplegia, and aphasia; tendency to improvement and relapse; there may be paralysis or unconsciousness, optic neuritis. The diagnosis is made by a Wassermann reaction, which must be positive.

Treatment consists of inunctions of mercury (either the ointment or the oleate) or intramuscular injection of a mercurial salt; potassium iodide, either alone or in combination with mercury; sulphur baths are said to aid the elimination of the mercury from the system. Small doses of salvarsan have been recommended by some.

10. "*The treatment of acute articular rheumatism* consists in rest of the parts, and the patient should lie between blankets. The joints should be enveloped in soft wool or flannel. Restricted diet is essential. Fractional doses of calomel (gr. ¼ every hour for 6 hours) should be administered, followed by a saline purgative. Salicylic acid or its derivatives may be given in full doses, and diuretics are especially indicated. Hyperpyrexia may be controlled by phenacetine (gr. 5.). During the convalescence, tonics are of decided advantage. Locally, lead-water and laudanum or belladonna liniment may be used. The diet should be carefully regulated." (*Pocket Cyclopedia.*)

Dermatology, Syphilology, and Diseases of Eye, Ear, Nose, and Throat.

1. *Psoriasis* "is a common chronic inflammatory disease of the skin, characterized by variously sized lesions, having red bases, covered with white scales resembling mother-of-pearl. It affects by preference the extensor surface of the body. The lesions are infiltrated, elevated, clearly defined, covered with white, shining, easily detachable scales which, upon removal, reveal a red, punctate, bleeding surface. The eruption is absolutely dry, and itching is usually absent."

"*The treatment* consists of the internal administration of arsenic, cod-liver oil, oil of copaiba, or potassium iodide, and the use of local applications. The scales should be removed by soap and water, alkaline baths, or oily substances. Ointments containing salicylic acid (3 per cent. to 10 per cent.), tar (℥ 1 to ℥ 1 of ointment), ichthyol (℥ 1 to ℥ 1), chrysarobin (gr. 20 or 30 to ℥ 1), ammoniated mercury (gr. 15 or 20 to ℥ 1), etc., are very beneficial, and should be used after the scales have been removed." (*Pocket Cyclopedia.*)

2. Pruritus ani is a frequent sign of hemorrhoids, diabetes mellitus, thread-worms, and fissure of the anus.

3. A patient may be considered cured of gonorrhea in the continued absence of discharge, gonococci, and shreds.

4. *Signs and symptoms of congenital syphilis.*—Impeded breathing, snuffles, necrosis of nasal bones, erythematous rash on buttocks, general atrophy with a wizened "old man" appearance, fissures of lips and angles of mouth, mucous patches in the mouth, condylomata, hemorrhages under the skin, onychia, enlargement of spleen, prominent forehead, Hutchinson teeth, interstitial keratitis, periostitis, and gummata of the internal organs.

5. *Treatment of syphilis.*—Intravenous or intramuscular injection of Salvarsan in dose of 0.5 gram, to be repeated twice at intervals of a fortnight. Intramuscular injection of calomel or administration of mercury with chalk by mouth. Iodide of sodium or potassium must also be administered during the second year. This may be combined with the mercury by the administration of the protiodide of mercury. Sometimes mercury may be given by inunction. The patient must have his teeth attended to, use a mild antiseptic mouth-wash, and should give up alcohol and tobacco. Calomel or iodoform may be used as a dusting powder for the chancre.

6. *The dangers of acute suppurative inflammation of the middle ear* are: Chronic purulent otitis media, perforation of ear drum, boils of external auditory meatus, ankylosis or necrosis of ossicles, mastoiditis, facial paralysis, meningitis, thrombosis of lateral sinus, abscess of brain or cerebellum.

7. *Trachoma* is an inflammatory condition of the conjunctiva, accompanied by hypertrophy, granule formation, and subsequent cicatricial changes.

Etiology.—It is caused by contagion from another eye, being transferred by means of the secretion.

Treatment "consists in an attempt to reduce the inflammatory symptoms and secretion, and to check and remove hypertrophy of the conjunctiva, thus shortening

the duration and diminishing the liability to conjunctival cicatrization and to sequelæ. This is accomplished either by the use of certain irritating applications or by mechanical (surgical) means.

Irritating applications.—Sulphate of copper in the form of a crystal or pencil is the favorite local application. Nitrate of silver (1 or 2 per cent. solution), gylcerole of tannin (5 to 25 per cent.), and the alum stick are also employed.

Mechanical (surgical) treatment includes expression, grattage, excision, curetting, electrolysis, *x*-rays, and galvanocautery." (May's *Diseases of the Eye.*)

8. *Tuberculous laryngitis* is generally secondary to pulmonary tuberculosis. The mucosa of the larynx is swollen, and small tubercles may be found on the vocal cords. The tuberculous masses caseate and ulcerate; the pharynx, epiglottis, and trachea may become involved by extension. The signs and symptoms are those of the primary tuberculosis, with the addition of hoarseness, dyspnea, and dysphagia.

9. *Acute suppurative inflammation of the frontal sinus* is treated by opening the sinus by an incision along the inner part of the eyebrow, and then by trephining and curetting the wall of the cavity; the infundibulum is enlarged, and a drainage tube inserted for a few days; the cavity is then washed out daily, through the nose, till all discharge has ceased.

10. *Nasal polypi*, if mucous, are to be removed by a wire snare; if they recur, the bone should be curetted; if there is much bleeding, the nasal cavity is to be packed with gauze for twenty-four hours. In case of fibrous polypi these must be scraped away; but treatment is only possible in the early stage.

OBSTETRICS.

1. Conditions that justify the induction of premature labor: (1) Certain pelvic deformities; (2) placenta prævia; (3) pernicious anemia; (4) toxemia of pregnancy; (5) habitual death of a fetus toward the end of pregnancy; (6) hydatidiform mole; (7) habitually large fetal head.

2. *Positive signs of pregnancy:* (1) Hearing the fetal heart sound; (2) active movement of the fetus; (3) ballottement; (4) outlining the fetus in whole or part by palpation; and (5) the umbilical or funic souffle. *Doubtful signs of pregnancy:* (1) Progressive enlargement of the uterus; (2) Hegar's sign; (3) Braxton Hick's sign; (4) uterine murmur; (5) cessation of menstruation; (6) changes in the breasts; (7) discoloration of the vagina and cervix; (8) pigmentation and striæ; (9) morning sickness. *Subjective signs of pregnancy*, in the order of their appearance, are: Cessation of menstruation, morning sickness, increased frequency of urination, active fetal movemets. *Objective signs of pregnancy*, in the order of their appearance, are: Softening of the cervix, changes in the mammary glands, discoloration of the vulva and vagina, pulsation in the vaginal vault, Hegar's sign, active fetal movements, ballottement, palpation of the fetus, intermittent uterine contractions, hearing the fetal heartbeat, rate of growth of the uterine tumor.

3. *Symptoms of death of the fetus* during the later months of pregnancy are: Cessation of the signs of pregnancy, the abdomen and uterus are both diminished in size, the fetal heart sounds and movements cease, there is no pulsation in the cord, the mother's breasts become flaccid and occasionally secrete milk. If the fetus has been dead for some time crepitus of its cranial bones may be elicited.

4. *Curettage is indicated:* (1) For removal of placental débris (2) in hemorrhagic endometritis, (3) in some forms of dysmenorrhea (membranous), (4) for diagnostic purposes, (5) in some cases of puerperal sepsis, (6) sometimes to check hemorrhage, due to fibroids. *Contraindications:* (1) The least suspicion of even the possibility of pregnancy; (2) menstruation; (3) acute endometritis; (4) malignant disease of the uterus or vagina; (4) acute pelvic inflammation.

Technique.—All antiseptic and aseptic precautions are necessary, the patient should be in the dorsal position, the vagina is to be disinfected, and the cervical canal dilated; a speculum is introduced into the vagina and the cervix is drawn down with volsella; the uterine cavity is irrigated with creolin or lysol; a curette is inserted to the fundus and moved down to the internal os; the operator should begin at one cornu and go in the same direction all around till he reaches the starting point, and if necessary repeat till no more spongy or hyperplastic tissue appears; the fundus should be scraped separately by moving the curette along it from side to side; in going toward the fundus no scraping should be done, and care must be taken not to perforate the uterus; should this happen no fluid must be injected; otherwise the uterus and vagina are again irritated, and one or more strips of iodoform gauze are inserted into the cavity to act either as a hemostatic plug or as a drain, which is diminished with two days' interval and withdrawn on the sixth day. A hemostatic tampon should be placed in the vagina and withdrawn the following day. If any fever arises, the tampon is at once removed and the vagina douched with antiseptic fluid every three hours. If not, the vagina is only swabbed with the same every day, and packed loosely with iodoform gauze. After the final removal of the gauze the antiseptic douche is given twice a day until there is no more discharge. The patient should remain in bed for a week.

5. Labor is divided into three stages: The *first stage* begins with the commencement of labor, and ends with the complete dilatation of the os uteri. The *second stage* begins with the complete dilatation of the os uteri, and ends with the birth of the child. The *third stage* immediately follows the second, and ends with the expulsion of the placenta and the beginning contraction of the uterus.

In the *third stage of labor* the physician should seize the fundus of the uterus through the abdominal wall and knead and rub it until it contracts vigorously; then he should press it down in the direction of the axis of the pelvic inlet. This should last for about a quarter of an hour after the child is born. The placenta, after it is expressed, should be carefully taken by the physician so as to be sure that it is *all* expelled; at the same time care must be taken that no particle of membrane remains behind. Fluidextract of ergot may be administered. The *dangers* are: hemorrhage; retained placenta or clots or pieces of the membranes and sepsis.

SURGERY.

1. *Shock* is the name given to a sudden and general depression of the vital powers; due to some strong stimulation (such as injury or emotion), acting on the vital centers in the medulla and producing vasomotor paralysis. Shock is *primary* when the symptoms appear promptly; it is *secondary* when the symptoms don't appear for several hours (often observed after railway accidents, intoxication, etc.)

Symptoms of shock.—The blood pressure is lowered considerably; the pulse is very compressible, rapid, short, and often difficult to count; the respirations are quick, sighing, and irregular; the skin is cold, clammy, and pale; perspiration may be profuse, but other secretions are diminished; body temperature is subnormal; muscles are relaxed; and reflexes are diminished.

Treatment.—Place the patient in the recumbent position, with the head low, apply warmth to the body, administer a stimulant, and give a hot saline infusion; morphine, hypodermically, may be necessary for the relief of pain. Adrenalin solution is administered into the arterial system.

In surgical operations *shock may be largely prevented* by reassuring nervous patients, keeping the patient warm, the avoidance of the excessive catharsis, and semi-starvation that often prevails before operation, the administration of strychnine and atropine before operation, the avoidance of delay and undue handling of parts during the operation, prompt checking of hemorrhage, and by using the utmost gentleness.

2 *Acute suppurative appendicitis* begins suddenly with pain about the umbilicus or right iliac fossa, vomiting, constipation, and slight fever. There is some tenderness at or about McBurney's point, a spot at the junction of the outer and middle thirds of a line joining the umbilicus and anterior superior iliac spine, and rigidity of the right rectus muscle.

A well-marked swelling is usually present, and the pulse steadily increases in frequency. There is also a steadily-increasing leucocytosis. A persistently high temperature, or a subnormal temperature with an increasing pulse-rate, are strong indications as to the presence of pus. Three terminations may occur: 1. The attack may subside, leaving the pus shut up. 2. The abscess may point and discharge itself into the bowel or on the surface, or it may track upward along or behind the colon, and form a subphrenic abscess. 3 The localized abscess may burst and cause general peritonitis. The rectum should always be examined, as a collection of pus may be felt in Douglas's pouch.—(From *Aids to Surgery.*)

Diagnosis.—This is made by the sudden and severe

abdominal pain, unilateral rigidity of lower part of abdominal wall, tenderness over McBurney's point, with nausea, vomiting, fever, and leucocytosis.

In *distended gall-bladder.*—The pain is more severe and sudden, and is in the region of the liver; it radiates to the right scapula and toward the umbilicus; chills and sweats are common; also vomiting, and sometimes symptoms of collapse and jaundice; all the symptoms come on more suddenly. In *gallstone colic.*—The pain is excruciating and is in the region of the liver; it radiates to the right scapula and toward the umbilicus chills and sweats are common also vomiting, and sometimes symptoms of collapse and jaundice; calculi may be found in the feces. In *ulcer of the pylorus*, the pain is in the epigastric region, may radiate to the left shoulder, and is increased by taking food (usually about one to three hours after a meal); vomiting may occur from one to four hours after eating; hemorrhage may be present; the acidity of the gastric contents is above normal, owing to excess of free hydrochloric acid. In *renal colic.*—The pain is in the region of the affected kidney; it radiates down the thigh; there are intense rigors, retraction of the testicle may be present, also history of previous attacks or of calculi; the urine may be scanty, suppressed, or bloody. In *acute peritonitis.*—Both thighs are flexed, pain and tenderness are more general and are increased by movement, vomiting is frequent, the abdomen in general is distended and is tense and tympanitic.

Salpingitis is diagnosed by: A dragging sensation in the neighborhood of the affected tube; colicky pain, which is increased on exertion or even on standing; abdominal tenderness; menstrual disorders, as amenorrhea, metrorrhagia, dysmenorrhea, menorrhagia; dyspareunia; there may be septic symptoms and peritonitis; sterility generally ensues. On examination there will be found a fulness in Douglas's pouch and one or both lateral fornices; in these latter will be felt either the tubes, distorted and possibly adherent, or a sausage-shaped tumor, which is very painful; the uterus is retroverted or retroflexed, and may be bound down by adhesions; there may be an intermittent expulsion of pus accompanied and preceded by a burning pelvic pain. In *ovaritis* the pain is not localized, but spreads to the vagina and rectum; it is usually worse just before the menstrual period, which sometimes affords relief; on vaginal examination the ovary is found to be tender.

Treatment.—"Where pus is present or suspected, the abdomen should be opened over the swelling, and in most cases it will be found that there are adhesions to the anterior abdominal wall, shutting off the abscess cavity from the rest of the abdomen. A finger should be gently inserted to feel for and remove a concretion or the appendix; but no prolonged search should be made for the appendix for fear of breaking down the adhesions. A large rubber drainage tube should be inserted, and the cavity will soon become clean and heal by granulation. If, when the abdomen is opened, no adhesions to the anterior abdominal wall are found, the cavity should be protected with gauze packing. The abscess will then be found among a mass of matted omentum and intestine, and can be opened by gently separating them. A drainage tube is inserted and the gauze packing is left in for three days. By that time firm adhesions have formed and the peritoneal cavity is safe from infection.

"When general peritonitis is present, the abdomen must be opened and drained and the appendix removed; but these cases are almost always fatal.

"In any case in which the symptoms are excessive, especially with a rapidly increasing pulse rate, an operation should be done, as this gives the only chance in cases where there is suppuration without adhesions, especially in those cases due to perforation or gangrene.

"*Operation for removal of the appendix.*—An incision is made at right angles to a line (at the junction of the outer and middle thirds) joining the umbilicus and anterior superior iliac spine, one-third being above and two-thirds below it. The cecum is found, and the anterior longitudinal band is traced down to the appendix, which usually comes off from the inner side and runs inward and downward. If not found there it should be looked for in the retrocecal pouch or on the outer side of the cecum. The meso-appendix should be ligatured and cut through, a collar of peritoneum turned back, and the mucous and muscular coat ligatured near the base and cut off. The peritoneum should be stitched over the stump, and then the stump should be invaginated into the wall of the cecum by running a purse-string stitch around it."—(*Aids to Surgery.*)

Aftertreatment.—This is mainly negative. "The patient should be fed by nourishing enemata, and water should be supplied by continuous proctoclysis, which may be repeated whenever thirst reappears. In case of severe shock subcutaneous injection of from 500 to 1000 c.c. of normal salt solution should be administered. In suppurative cases the Fowler position is indicated. In cases of *nausea* or *vomiting* or *gaseous distention* of the abdomen, the pharynx should be cocainized and gastric lavage should be practised. This should be repeated whenever these conditions recur. In case of pain, from 10 to 30 drops of deodorized tincture of opium dissolved in 100 c.c. of normal salt solution should be given by rectum as often as necessary to keep the patient comfortable. So long as no nourishment is given by mouth, opium given in this manner is perfectly harmless. It is well for the patient to chew gum in order to prevent parotitis."—(*Cyclopedia of Medicine and Surgery.*)

3. *Colles' fracture* is a transverse fracture at lower end of radius; it is due to falls on the outstretched palm. The line of fracture is about an inch above the wrist, and runs obliquely downward from behind. The lower fragment is driven backward and upward, and rotated to the radial side, carrying the hand with it into the position of abduction and leaving the tip of the radius at the same level as, or higher than, the tip of the styloid process of the ulna. The internal lateral ligament of the wrist is ruptured or the styloid process torn off. The fracture is usually impacted, the upper fragment being driven into the lower. The deformity is characteristic, *viz.:* (1) The hand is abducted; (2) the styloid process is on the same level as, or lower than, the tip of the radius; (3) the upper end of the lower fragment projects above the back of the wrist; on the front is a corresponding depression, while above it the upper fragment projects forward. Union occurs readily, but it is common to get deformity and adhesions about the site of fracture. *Treatment:* Disimpaction and reduction are brought about by grasping the hand by the "shaking-hands" grip, extending and adducting the hand and lower fragment. The arm is then fixed on a splint. It is very important in this fracture to start massage and passive movement not later than the end of the first week, to prevent stiffness. Union is firm in three weeks.—(*Aids to Surgery.*)

4. Hip Joint Disease.—*Symptoms of first stage:* Night cries, lameness in the morning; a slight limp; tendency to become tired on slight exertion; wasting; spasm; pain; swelling and deformity (either real or apparent).

Symptoms of second stage: Abduction; limping; pain, which is worse at night; apparent lengthening of the limb; abscess; atrophy of thigh muscles; flexion of thigh; effusion into hip joint; and there may be crepitation in the joint.

Symptoms of third stage: Flexion, abduction, and shortening of the limb; the joint may be dislocated or ankylosed, or suppuration may occur.

"The *cardinal symptoms* of hip-joint disease are the spasm, wasting, lameness, deformity (real and apparent), pain, and swelling. Careful attention to these will make the diagnosis easy. The tendency of the disease is toward recovery, but the prognosis is greatly influenced by the age, type of disease, complications, and treatment. Death usually occurs from amyloid changes in the viscera.

"*Constitutional treatment* consists of improved hygiene, good food, fresh air, and the administration of tonics, such as iron and the hypophosphites, and alteratives, such as cod-liver oil, iodine, and its salts. A change of climate is sometimes beneficial. Locally, iodine, blisters, hot-water bottles, or hot-water dressing may be applied.

"The *special treatments* consist of the mechanical treatment, treatment of the complications, and the surgical treatment. The mechanical treatment consists of recumbency for two or three weeks in uncomplicated cases, with fixation and traction. Continuous traction may be first obtained by Buck's or Savre's extension apparatus, made of adhesive plaster, later by means of a traction splint, with crutches, and still later by the traction splint alone, a high shoe being worn on the sound side, which in a year or two may be discarded. A modified traction splint may be made of plaster of Paris. Differences of opinion exist as to when the abscesses should be incised, but always the strictest asepsis or antisepsis is necessary. Irrigation of the cavities with sterile water, boric acid solution, or mercuric chloride solution, 1:4000, and the injection of sterile

iodoform oil, 5 to 10 per cent., are commonly resorted to. Osteotomy and fixation may be required for the deformity arising as a complication. The surgical treatment consists of aspiration, incision, erasion, and excison."—(*Pocket Cyclopedia of Medicine and Surgery.*)

5. GUNSHOT WOUNDS. Regarding *probing*, Da Costa says:—"The surgeon must not feel it his duty to probe in all cases. In many cases it is better not to probe at all. Explore for the ball when sure that it has carried with it foreign bodies; when its presence at the point of lodgment interferes with repair; when it is in or near a vital region (as the brain); and when it is necessary to know the position of the bullet in order to determine the question of amputation or resection. If the wound is large enough the finger is the best probe."

Regarding *immediate operation*, there is difference of opinion, some authorities holding that unless the bullet causes definite symptoms it should be let alone; others advocate its removal to relieve the mind of the patient and to obviate possible complications later on.

Gunshot wound of the knee should be treated conservatively, if possible; the wound should not be explored except to remove foreign bodies, loose fragments, etc. Incision may be necessary for such removal. The joint is irrigated with a weak antiseptic solution, drained, dressed, and immobilized. Suppuration calls for incision and drainage. If there is extensive laceration of tissue with much splintering of bone and interference with blood and nerve supply the condition may call for amputation.

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†	
Alabama*	W. H. Sanders, Montgomery	Mootgomery	Jan. 9
Arizona*	J. W. Thomas, Phoenix	Phoenix	
Arkansas	T. J. Stout, Brinkley	Little Rock	Nov. 11
California	C. B. Pinkham, Sacramento	Los Angeles	Oct.
Colorado	David A. Strickler, Empire Building, Denver	Denver	Oct. 2
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	Nov. 14
Delaware	J. H. Wilson, Dover	Dover	Dec. 12
Dist. of Col'bia.	E. P. Copeland, Washington	Washington	Oct. 10
Florida*	E. W. Warren, Palatka	Palatka	Dec. 5
Georgia	C. T. Nolan, Marietta	Atlanta	Oct. 10
Idaho*	Charles A. Dettman, Burke		Oct. 4

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State.

Privileged Communications.—In an action for personal injuries, testimony of a physician as to whether the plaintiff was intoxicated was held to be excluded where the doctor was called to attend the plaintiff as a physician and became possessed of his information through his professional employment.—N. Y. C. & St. L., Indiana Supreme Court, 112 N. E. 762.

Therapeutic Hints.

Plantar Hyperhidrosis.—

℞ Acidi tannici, ʒj.
Aluminis, ʒv.
Aquæ, ℥xxx.
M. fiat lotio.
Sig.: Apply once or twice daily.

If a fetid condition exists, a foot bath containing potassium permanganate 1 1000 may be used for ten minutes every three days. In the meantime stockings may be powdered with the following:

℞ Pulveris talci, ʒx.
Bismuthi salicylatis, ʒj.
Zinci oxidi, ʒv.
Pulveris aluminis, ʒiiss.
M. fiat pulvis.—*Gazette des Hôpitaux.*

Treatment for Burns, Scalds, and Wounds.— Soubeyran prefers the following prescription for use in the treatment of scalds, burns, varicose ulcers, etc.:

℞ Balsami peruviani, ʒx.
Acidi picrici, gr. vij.
Paraffini mollis, ʒij.
M. fiat unguentum.

Care should be taken to protect clothing and bedclothes from the stains which the above drugs produce.—*Journal des Praticiens.*

Dandruff.—The following prescription, while not new, deserves repetition because of its ability to produce such excellent results:

℞ B. naphthol, gr. xx.
Bergamot oil, m. x.
Vaseline, ʒj.
M. fiat unguentum.

Apply to the scalp at night and thoroughly shampoo the scalp and hair in the morning with any good soap.—*Practical Prescribing and Treatment.*

Pneumonia Treatment.—

℞ Potassii iodidi, ʒj.
Creosoti, ʒss.
Spiriti recti, ʒij.
Extracti glycyrrhizæ fluidi, ʒiij.
Aquam ad, ʒvi.
M. sig.: A tablespoonful every four hours until the temperature reaches normal.

Trifacial Neuralgia.—

℞ Morphini hydrochloridi, gr. 1 6.
Antipyrini.
Potassii bromidi, āā, gr. ix.
Acidi citrici, ʒss.
Acidi tartarici, gr. xl.
Sodii bicarbonatis.
Sacchari lactis, āā, gr. LXXV.
M. et fiat chartula No. 1. Sig.: Take in a half glass of water.—*Nouveaux remèdes.*

An Easy Remedy for Constipation.—Bran biscuits made according to the following directions and eaten with meals until the desired action of the intestines is obtained will assist in the treatment of and in many cases entirely correct constipation: Bran 3½ oz., agar 90 gr. or ½ oz., eggs 2, salt to taste; put the agar into a small dish, cover with a cup of water and boil until dissolved; while this is still boiling hot, the *warmed* bran is stirred into it to make a thick batter; beat the eggs until very light and add to the batter together with a little sugar and the salt. Chocolate flavoring may be added if desired, and the mixture is then poured into gem-pans and baked.—*American Journal of Nursing.*

SOME PRACTICAL NOTES ON BLOOD-PRESSURE*

BY GEORGE VAN NESS DEARBORN,

CAMBRIDGE, MASS.

PSYCHOLOGIST AND PHYSIOLOGIST TO THE FORSYTH DENTAL INFIRMARY FOR CHILDREN, BOSTON; INSTRUCTOR IN PSYCHOLOGY AND EDUCATION IN THE SARGENT NORMAL SCHOOL, CAMBRIDGE.

IN the course of somewhat slow observations (begun in the Hemenway Gymnasium, Harvard, 1913) on the relations of the mental process to the so-called "pressures" of the blood in the arteries (in reality, of course, there is but one every-varying pressure), such extensive variability was obvious in young and old, male and female, strong and weak, normal and abnormal, that it became almost a duty to report it to the rank and file of medical practitioners—men and women too busy, for the most part, to learn these matters for themselves.

Much as we have supposed we knew about the significance of blood-pressure, a confidence almost inevitable in such a situation, I, for one, am convinced that it is only now that we are beginning to be really sure that the expression, "her blood was up," means something—but then not too much!

The origin of the present fad in regard to blood-pressure appears to be, in part, the old-fashioned notion, almost a proverb, that one is as "old as one's arteries"; in part, the common fear or phobia of apoplexy, which is now very commonly known by the laity to be due to the "bursting" of an artery in the brain; partly from the attention given Metchnikoff's decadent theory as to a means of keeping the arteries elastic; and, finally, in part from the very wide medical advertising of blood-pressure gages. The universality of this fad is really worth noting; the topic always excites almost "popular" interest among laymen, and in some cases it has been unduly catered to. An illustration of this was in one of Dr. Evans' excellent and famous talks on health (published as syndicate matter in some of the newspapers of importance), in which he advised an old gentleman who was worrying about himself to secure an instrument and measure his own blood-pressure; theoretically, of course, this advice is all wrong. We should never advise any one who is worried about himself to make any such quantitative study of his "condition."

The first thing we come to in discussing the blood-pressure fad, as we know it at the present time, is the mode of action of the mechanism for locally changing the diameter of arterioles. Vasomotion, it is certain at the present time, is a very complex and elaborate set of adaptations, which *requires careful and extensive study before we can know anything worth while about the true meaning of blood-pressure.* And yet I boldly propose to suggest certain of my own more practical gleanings out of this great, and, for the most part, untilled field; this inconsistency is in part its own punishment.

The methods of taking blood-pressure we will not discuss here, as you are probably all familiar with them. I merely suggest that the auscultation method is the one now used. For the systolic readings, the Korotkoff sound is extremely exact, provided one uses as the indicator a constancy of rhythm—disregarding the first sporadic sounds so frequently observed. For the diastolic determinations, the Korotkoff sounds are far less accurate, but still by far the best means that we have, save in those cases in which (perhaps owing to a dilator-spasm in the artery?) the third and fourth-phase sounds wholly and suddenly disappear. In the forty-eight hundred measurements made by the writer, this phenomenon has been observed many times, and its occasion as well as its cause is an interesting physiologic problem in itself, especially in its psychologic relations (which are the particular interest of the present researcher).

The heart rate is taken just before the blood-pressure measurements are begun; always at the end of the sitting, and as frequently as is expedient throughout the series of measurements. With an inexpensive stop-watch this can be readily done and recorded in twenty seconds, so that these measurements do not at all disturb the series of systolic and diastolic measurements, both made every minute, or, if preferred, every two minutes.

Gradually to get down to our main thesis, there are at least two dozen *normal* things already appreciated as determinants of blood-pressure readings as they are commonly made by the average physician. These twenty-four normal modifiers and determinants may be merely mentioned, their order here not being significant. (1) First, there are the still unknown and very complex vasomotor changes, more or less important. (2) Emotional tones (pleasantness and unpleasantness), and especially anxiety. (3) Muscular tonus, especially of the lower muscle tissue of the upper arm. (4) The relative rigidity of the arterial wall, this essential hardening coming from the physiological vasoconstriction of the artery as well as from its pathological induration. (5) The either arched or broken-arched condition of the brachial artery at the moment. (6) The position of the individual, usually either standing, sitting, or reclining. (7) Whether the right or the left arm be measured. (8) The heart rate. (9) Movements of any part of the arm. (10) The recency of physical exercise, this feature being, in part, one of the local brachial agencies, and in part one of general nervous excitement; and into this

*The basis of remarks made to the Massachusetts Medical Society at its 135th annual session, June 6, 1916.

determinant comes to a considerable extent the degree of "training." (11) Vasomotor neurosis, which has been hinted at, if not described, by Consorti, Cassirer, and others, and which I personally suspect to be far more common and important than is realized. (See charts.) (12) The recency of eating, for Professors Weysse and Lutz[13] have shown that the systolic pressure, on the average, is eight millimeters higher after eating. (13) The time of day. The systolic-pressure mean progressively rises during the day, while the diastolic apparently falls as the autonomic tonus lessens during the day. (14) In women, the menstrual period must be considered, the pressure being higher just before and in atonic women lower just after. (15) Age; in general, the pressure more or less evenly increases[6] up to about 65. (16) Sex; the pressures range a few millimeters lower in females. (17) Atmospheric heat, with humidity, seems sometimes to have a marked lowering influence over blood-pressure. (18) Voluntary relaxation of the body (à la Hindu) readily lowers it to a very marked extent (see the charts). (19) Involuntary and chronic mild collapse of the psychomotor organism (commonly designated as a condition of being "run down"). (20) the integrity and adjustment of the measuring instrument. (21) Breath holding; as the chart shows, in one case the systolic blood-pressure was raised 119 millimeters of mercury in 2½ minutes. (22) The integrity of the heart, especially of the mitral and the aortic valves. (23) Thinking, at least excited activity of the cerebral cortex, irregularly raises the systolic blood-pressure, while widespread, unexcited, more general brain action frequently lowers it. (24) This (in some respects, in the long run, the most important of all, perhaps) is what I shall have to call *the algebraic local, or else central balance of the neurochemical pressors and depressors*. These substances are largely internal secretions, the best known of which are adrenin and pituitrin; the most obvious depressors (Beifeld and colleagues) are extracts of the pancreas and of the salivary glands,[1] and very likely extract also of the pineal gland, the epiphysis. According to Beifeld, the increased irritability of the vasomotor centers produces always a very great lowering of blood-pressure. The intimate connections and integrations of the internal secretions, being investigated by Professor Cannon and his colleagues, are obvious; on the one hand, consider the relationship of these irritator and depressor internal secretions to the increased pressure in the condition designated as dynamogeny (due in part to an increased amount of sugar and of adrenin in the blood); on the other hand, they may explain in part the effects of that important trained voluntary relaxation at which the Orientals and Hindoos are especially expert, and surely much needed in our supervital American city life.

There are six kinds of uncertainty, at least, which enter into every blood-pressure test, inevitably:

1. In the first place, there is to be considered always *the muscle tonus of the arm*. The arm is a fluid, but it is not the "perfect fluid" of physics, and, therefore, the relative rigidity of the muscles and of the other tissues of the arm is continually changing, and thus causing uncertainty in every measurement made by the present crude methods.

2. There is always uncertainty as to the *degree of tonus of the artery wall*, and that whether the arterial wall be hardened physiologically by active vasoconstriction, or hardened pathologically by actual but passive sclerosis. It is obvious that both of these cases would lessen the arterial variability and resiliency, and so tend to raise the blood-pressure measurements above what they should be. The pressure inside of the artery is not nearly so great as the gauge-readings actually indicate, as Brooks and Luckhardt[4] have recently emphasized; in sclerosis, the error, I should judge, may well be 100 per cent.

3. A source of error in all blood-pressure tests is *the varying shape of the arterial cross-section* at any moment. When the artery is round it consists of arches, and, therefore, is very resistant to compression; but when the arterial arch has been broken, the tube becomes much more easily compressible. It is a theoretical point, whose precise importance remains to be worked out.

4. *The training index* (whether the individual has been exercising recently or not) is always a probable source of uncertainty.[6] It is obvious from the records which I have shown that even a small degree of exercise very materially raises the blood-pressure. Another respect in which the physical-training index comes into the matter relates to the promptness of the reaction from the exercise-raised blood-pressure to the rest-normal, in that trained individuals show a very quick reaction thither, while in the untrained it is very slow. The climbing of a flight of stairs is violent exercise!

5. *The excitement index* of the individual is a large yet an almost continual source of uncertainty. Most common in medical experience is the mild anxiety, plus the general excitement of having a medical examination; but, above all, true anxiety, worry, especially a feeling of hurried, agitated worry. Any of these, and especially all combined, serve actually to increase blood-pressure very many (often forty) millimeters above what it physiologically or pathologically really is.

6. Another uncertainty is *the cerebration index of the individual* (as to whether he is thinking actively or not). Many of my records show distinctly that active thought of any kind, irrespective of emotional tone, distinctly lowers or raises the blood-pressure.

7. Occasionally there is a dilator spasm of the artery, which immediately stops the "water-hammer" Korotkoff sounds,[11] and so makes impossible any determination of the diastolic pressure.

8. At times, the still undescribed vasomotor neurosis, which "boosts" high the blood-pressure for weeks at a time.

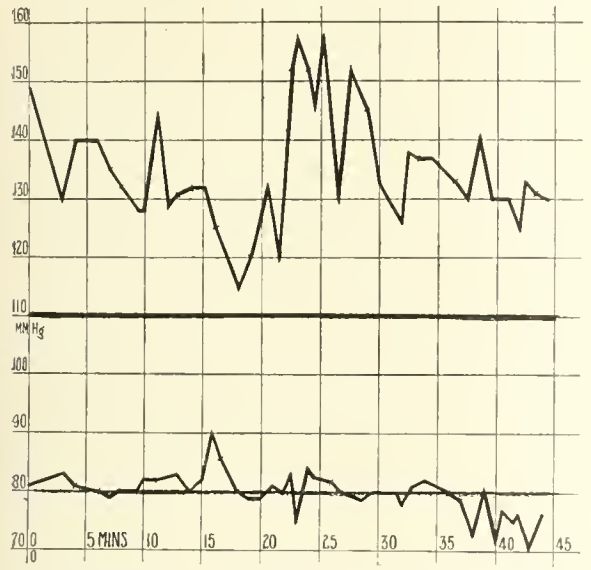
Whatever may be the explanatory physiology, one certainly finds at all ages a surprisingly large variability in the blood-pressure of the perfectly normal individual. I have been greatly surprised, as my measuring and experimental work has gone on, to see that this very wide variability, which naturally I thought at first to be exceptional, is not in reality exceptional, but common to all normal blood-pressure.

I have plotted 140 relatively continuous readings of blood pressure, systolic and diastolic, so far, ranging in time from a few minutes to something above one and a half hours; the figures of the protocols have been merely plotted. They represent a more or less chance selection of at least 4800 measurements of blood-pressure which I have personally made the last three years. I have arranged these charts in nine illustrative groups.

The first group, A, is to be used to exemplify the wide clinical initial variation, to show how widely the first measurement, made in a doctor's office, may vary in some cases from the mean at that visit;

often (and this, too, without any apparent cause whatever other than those noted) it is thirty or more millimeters.

Group *B* consists of three records, which show a progressive fall of blood-pressure from the initial



HEMOBAROGRAM 1.—This patient was a woman nearly sixty years old, normal, but typical of the Yankee women, who are always busy and usually worrying about something, imaginary or real. The variations here are wholly spontaneous, with a systolic maximum of 42 mm. Hg in 5 minutes and a diastolic maximum of 15 mm. Hg in 7 minutes. The diastolic curve shows the relatively small variation characteristic of the arteries after fifty years. The heart-rate remained about 60.

measurement. In one case, *B*1, with no apparent cause at all, except those already considered, there was a fall of 46 millimeters in 13 minutes. Do the rank and file of the country's clinicians outside the scientific societies discount such a change and give their patients, in any event, the great benefit of the great doubt? I should fear that they as yet do not do so.

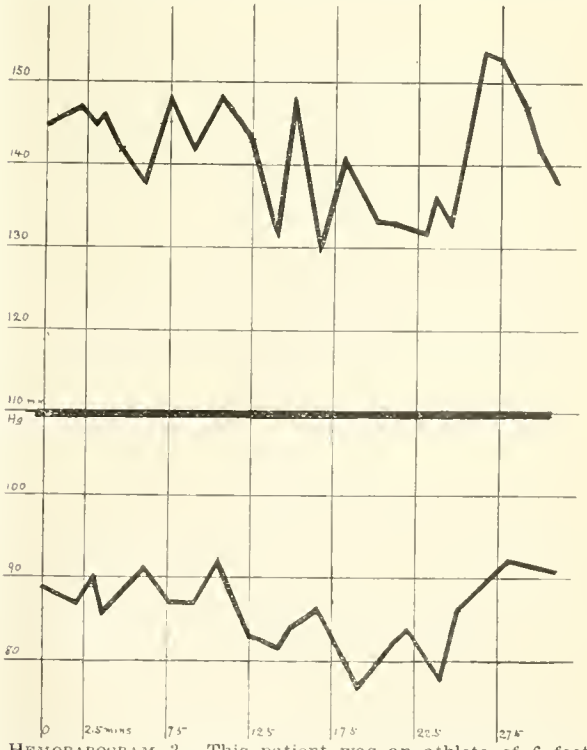
The third group, group *C*, demonstrates the extreme rise of systolic pressure during exercise, and the fall after exercise is concluded. For example, going rather fast up a single flight of stairs but not more quickly than many people habitually climb stairs, will make a rise of blood-pressure from 20 to 30 millimeters; and then add hurry, excitement, and anxiety—!

The fourth group, group *D*, demonstrates a few of my preliminary records of influence of some of the mental conditions on the blood-pressure. It may be seen even from these preliminary charts that the mental, especially affective, influences are both quick and powerful; 20 millimeters upward is no uncommon rise from a spontaneous, unpleasant thought or unpleasant momentary grief; 30 odd millimeters is often seen in records when the grief is recent and acute, for example, in the case of a young woman whom I quite unintentionally reminded of the recent death of her mother. But do observe that such memories (and others far different, but not less dynamic) are liable to come into the minds of patients in your own offices, at any instant, thus entirely destroying the significance of the measurement.

The fifth group, group *E*, of these blood-pressure records demonstrates how easy and powerful is voluntary relaxation, on one hand (lowering the pressure), and, on the other hand, holding the breath (which raises the pressure). The most noteworthy of all these particular records (Fig. 4) is that of a medical man in a suburb, a man in first-class physical condition and nearly fifty years old, who voluntarily reduced his pressure in fifteen minutes from his general basis of 135 to 111 mm. Hg; and then raised it in the course of two and one-half minutes of breath holding to 230. It is obvious that this marked lowering of blood-pressure by a voluntary relaxation might be used by unfit and unscrupulous candidates for life insurance to make a false reading, unless readings be taken seriatim, many times and systematically.

Group *F* of these records shows how very considerable the normal variation is at all ages, in both sexes, and in the diastolic as well as systolic. The systolic average variation is 15 or 20 millimeters at least, and the diastolic pressures vary only less. Especial attention is called to the record (Fig. 1) of a woman about 59, perfectly "normal" so far as is known, but of a type popularly known as "a nervous woman." Her systolic pressure spontaneously varied 43 millimeters within eight minutes, and her diastolic pressure 15 millimeters within seven minutes. In another case, a perfectly normal and beautifully trained athlete, nearly 42 years old (Fig. 2), showed a spontaneous diastolic variation around 13 millimeters within three minutes, and within seven minutes a fall of 18 millimeters. In an active girl of 16 2/3, the diastolic fell (as shown by ten measurements) (Fig. 2), 23 millimeters in fourteen minutes; and so on more or less in every one's arteries always, life without end!

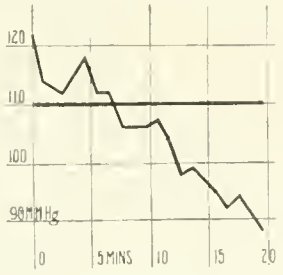
The seventh group, group *G*, shows that the systolic blood-pressure in nitrous-oxide anesthesia



HEMOBAROGRAM 2.—This patient was an athlete of 6 feet and 42 years, in fine condition. The heart-rate remained between 88 and 85. The first marked systolic variation coincided in time with the turning of his attention to the measurements being made. The last marked rise (21 mm. Hg) was due to the exertion of ascending a flight of ordinary stairs. In these charts the long rhythm of the arterial tension is obvious as well as a parallelism between the systolic and the diastolic series.

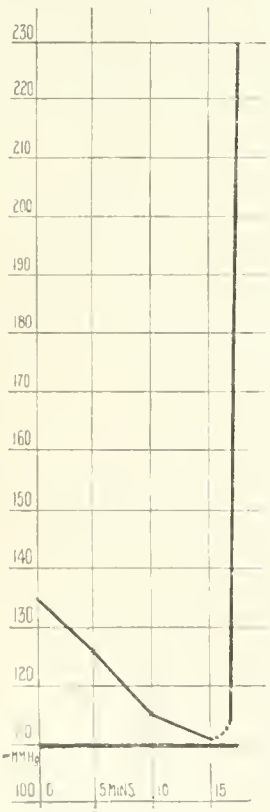
takes a small rise. The "authorities" differ in regard to this, most supposing that this anesthetic raises it to some extent. The work which I have done on this matter in the Forsyth Infirmary indicates that nitrous oxide produces a rise of blood-

pressure about equal to the exertion of going up a flight of stairs, but that it may be almost instantly reduced to normal, and kept at normal, by the proper admixture of oxygen. It seems to be agreed at the present time that nitrous oxide, mixed with oxygen,



HEMOBAROGRAM 3.—This systolic record was made from a normal girl of 10 years 4 months. It shows a fall of 34 mm. Hg. in 19 minutes; the heart-rate meanwhile stayed up to its initial 128 for seven minutes and then fell gradually to 104 at the end. The chute is plainly, in a way, an index of the patient's loss of apprehension and occurs in adults as well as in children!

produces no rise at all worth noting, and certainly no lowering. A chart in this group well shows how instantaneous is the control of the systolic blood-pressure by the addition of oxygen to this anesthetic. (Ether, as is well known, makes a marked rise in systolic; chloroform makes a marked fall, owing to its typical depression of the heart action. Cocaine produces a general rise of blood-pressure. It is possible at least that it produces this effect by its inhibition of the depressor[1] salivary secretion, thus allowing the adrenin or what not in the blood to raise the pressure.)



HEMOBAROGRAM 4. — A rugged doctor of medicine and athlete of 49 years 6 months. During the first 15 minutes he actively relaxed, muscularly, nervously, and mentally, and lowered his systolic brachial-artery tension 24 mm. Hg. Then he held his breath for 2.5 minutes and his pressure went up, very rapidly at last, to 230 mm. Hg, a rise of 119 mm. (July 19, 1915.) Not everyone could raise their arterial tension thus, but there are few who could not so lower it (often with great benefit) did they try.

Group *H* is a tentative set of records from mentally defective adults, morons, imbeciles, and idiots, as graded by the Binet, or, less often, by the coming-in point system of Yerkes. I am not ready to report this preliminary work as yet, but its psychologic interest is very great, and bids fair to furnish a key to the mental influences.

Group *J* of these records shows the least variation which can be found in my records made from normal persons. It is seen that even under these circumstances the systolic variation is, on the average, 8 or 10 millimeters at the lowest, and more or less rhythmic. There is obvious a tendency to a regular rhythm, with a double-vibration period of from two or five minutes. In general "all kinds" of rhythms are to be seen suggested in these hemobarograms, and it is as yet far too early to suggest either their numerical natures or their etiology. Inthis group, *J*, where the emotional, et al., variability is relatively small, the rhythms appear most plainly. Rhythm, of course, is inevitably inherent in all vegetative muscle, and its relation to the rhythmic action of the pressor and the depressor ductless glands has enticing interest for men in the promising vivisectional work, already so productive of useful knowledge.

A *summary survey* in brief of the charts shows:

1. Extreme and still unaccountable variations in the blood-pressure, both systolic and diastolic, in both adults and children.

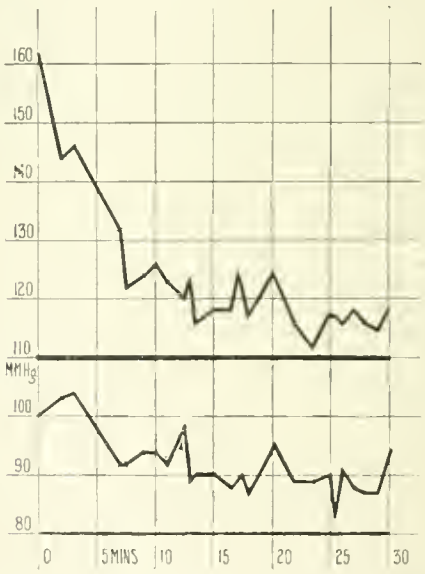
2. Blood-pressure is raised by tones of unpleasantness, and notably by anxiety.

3. In some cases, but by no means in all, it appears to be lowered by all relaxing pleasant feelings and pleasurable sensation.

4. It is raised by ideational brain action, especially by the voluntary work of the entire cortex.[9,10]

5. The blood-pressure appears to be an index of anxiety in the person's mind, conscious or subconscious, and may be so used, to some extent, for diagnostic purposes in psychopathology, etc.

6. The blood-pressure is, in general, as variable in adults as in children; in fact, the widest normal variation I have ever seen was in an individual,



HEMOBAROGRAM No. 5.—This is the thirty-minute record of a woman of 42 years who tests only 1.6 years on the Yerkes point-scale system of tests. When the cuff was first distended (170 mm. Hg.) she burst quietly into tears, emotionally shocked at the novelty of the painless sensation. Within the next 13 minutes her systolic brachial-artery tension had fallen to 46 mm. Hg., her diastolic 11 mm., her heart-rate falling meanwhile from 112 to 88, where it remained. Within seven minutes from the beginning she was in her usual good humor. This record, typical of the hemobarograms of mental defectives, is presented solely to illustrate the physiological "limit" of blood-pressure rise (due purely to office-apprehension) and its spontaneous fall under the more usual office conditions. Very many persons, both adults and youths, some of whom would "test up" rather better than 1.6 years Yerkes', show just this kind of blood-pressure phenomenon—however little the "rank and file" of physicians as yet realize it.

apparently normal, who was approaching the age of sixty.

7. There is a marked degree of reciprocity between different parts of the body.

8. The diastolic is as variable, in many cases, as is the systolic pressure.

9. The deliberate relaxation of the voluntary muscles readily and greatly lowers the pressure.

10. There are evidences of the frequency of a vasomotor neurosis[2-5] whose pressor effect is great and lasting enough to thoroughly mislead the clinician who mistakes it for the "anticipation of a nephritis," for arteriosclerosis, or for a sign of gout or of Raynaud's disease. Low blood-pressure sel-

dom has any sinister significance any more than has low heart rate.

11. Frequent suggestions, especially in the diastolic records, of a rhythmic pressure variation of from 15 to 30 millimeters in waves from ten to twenty minutes long.

But some of my readers certainly are asking, most naturally, two questions as they look back over this material.

First, "Is it not perfectly true, none the less, that each individual does have a consistent blood-pressure base or standard, whether there be such for every particular age or sex or not?" The answer is as obvious as the question: Certainly there is such a base for each person at any one time, but it is not easily determined in most cases.

The second question which might well be asked would be "Do not vascular (*i.e.*, interstitial) nephritis, arteriosclerosis, gout, obesity, Raynaud's disease, etc., have a high blood pressure, which stays up and stretches the arteries?" We may answer, with some promptness: Certainly, again, but with so many common idiopathic and wide variations, and with the likelihood of a perhaps purely vasomotor pressor neurosis, any one given measurement of this pressure is inadequate because uncertain.

There are certain theoretic corollaries which I may mention in regard to these observations: The need of a widespread, broad-minded study of vasomotion in its entirety, one of the very foundation functions of the intricate body marvel. Then we should know about the actual physics of the arm; more about the kinesthetic, perceptual, impulsive, emotional relations of the muscles of the arm and other parts of the body; and we should study the mental influence very much.

The blood-pressure in the brain is far more important than the very variable pressure in the arm, and means should be devised to measure the pressure there, where it is most important.

There are, too, certain practical corollaries or points which perhaps will interest the average practitioner more than do the foregoing theoretic desiderata:

1. Twenty minutes instead of one should be used in determining a blood-pressure, and the procedure should be carried out on several days, instead of on one day only, as is the common custom.

2. No one should interpret any measurement of the blood-pressure save as an algebraic balance of two dozen or so factors and modifiers.

3. A patient must not be acutely anxious or "scared." He must not be made to worry about anything, for anxiety raises the blood-pressure and may even sustain it indefinitely.

4. Keep in mind the frequent occurrence in persons of chronic-nephritis age of a pressor vasomotor neurosis—or at least something that acts like one.

In general, we may say, as a *conclusion*, too wide to be quite accurate, but perhaps, none the less, of some useful significance: Blood-pressure measurements, as they are taken at present by the majority of busy practitioners, are apt actually to be more misleading than significant; it is only by repeating the measurements each minute (or each two minutes) for a half hour or less, and on several successive days, care being taken in interpretation to avoid all known sources of high pressure, that one can be sure of having a significant set of measurements.

Addendum, August, 1916.—Extensive and substantial evidence derived from the numerous relatively continuous hemobarograms of this research, especially from their demonstration of the relative independence of the systolic and the diastolic pressures; from the muscular structure of the left lower heart (ventricle) and from its known volumetric movements; from the cerebral relations of the cardiac control in comparison with the autonomic neurology of the arteries; from the striking phenomena of the blood-tension observed in true emotions involving all parts of the body as compared with voluntary imitations thereof; from the observed relations of pressure to heart-rate; from the observed frequent vasodilator and vasoconstrictor "spasms"; from the phenomena of nephritic and sclerotic high diastolic tension; from Cannon's far-reaching work on adrenin, etc.; and from analogy—this evidence already makes it probable that the observed changes in the systolic pressure are chiefly due to variations in the size, and hence the systolic output, of the left ventricle, and that the diastolic variation in tension is primarily dependent on (arterial) vasomotion, the blood-pressure being always an algebraic balance of these two distinct but complementary sets of neuromusculo-glandular actions, and thus an index of the perfect integration of the organism.

THE PATHOLOGICAL AND THERAPEUTIC BEARINGS OF THE ELIMINATION OF BODY HEAT.*

By JOHN BENJAMIN NICHOLS, M.D.,

WASHINGTON, D. C.

In order to afford energy for the vital activities, oxidation of food and tissue material is constantly in progress in the living animal organism. Even when the body activities are at a minimum—during sleep—an unremitting supply of energy is required for carrying on the circulatory and respiratory functions. This constant oxidation results in continuous production of heat by the body, at the rate in the human adult per kilogram of body weight of from 1 to 4 calories per hour, according to the degree of muscular activity; or from 2,000 to 7,000 calories daily in a medium-sized subject of 70 kilograms (154 pounds) weight.

In order to maintain the temperature of the body at a uniform figure it is necessary that the heat generated be dissipated at a rate equal to that of its production. If the heat is dissipated more rapidly than it is generated, the body temperatlre will fall; if less rapidly, the heat produced must accumulate in the body and cause a rise in its temperature. A change of body temperature of 1° C. corresponds to 0.83 calory per kilogram of body weight. If the elimination of heat were entirely suspended, the body temperature would rise at the rate of over 3° F. per hour. These considerations indicate the constant necessity of proper elimination of the heat continually being generated by body oxidation.

The main means by which body heat or energy is discharged are three: (1) Radiation, conduction, and convection; (2) vaporization of water; and (3) external muscular work.

The elimination of heat by radiation, conduction, and convection is accomplished by the imparting of heat from the surface of the body to the surrounding atmosphere or other objects. This can be effected only when the temperature of the latter is lower than that of the body, and the rapidity of the heat discharge is proportional to the difference between the two. Ordinarily, the largest part of the body-heat elimination takes place by this way, about 75 per cent. of it being thus discharged under ordinary living and working conditions (temperature of 20° C.).

The loss of heat by evaporation consists in the absorption of heat by water when passing from liquid into gaseous form. Each gram of water vaporized and so excreted by the skin or lungs removes 0.59 calory of heat from the body. A large amount of heat is thus eliminated, the proportion varying according to the temperature and humidity of the air; ordinarily about 15 to 25 per cent. of the body-heat discharge occurs in this way.

The body energy gotten rid of in the form of external work accomplished (which can be measured in terms of heat) varies in proportion to the muscular activity of the subject, and ranges from zero to about 10 per cent. of the total heat discharge. As in the case of mechanical engines, only a fraction of the heat generated for the purpose reappears as actual work. For example, the mechanical efficiency of a steam engine is about 15 per cent.; that is, only 15 per cent. of the energy yielded by the burning of the fuel is converted into actual work. Similarly, the efficiency of the human body as an engine has been determined as from 9 to 24 per cent. It follows that for every calory of external work that is produced three to nine additional calories of extra heat are generated in the body and have to be eliminated.

An example of the relative magnitudes of the three main avenues of heat elimination is afforded by the calorimetric observations of Atwater and Benedict. The results of various tests made by them average (per diem per person) as follows (Bulletin 175, Office of Experiment Stations, U. S. Department of Agriculture, 1907, pp. 152, 179):

Table I

	Five Rest Experiments (10 Days)		Six Work Experiments (14 Days).	
	Calories	Per Cent	Calories	Per Cent
Heat or energy production (from oxidation of food and body material), as measured	2,258	....	5,179	....
Heat or energy eliminated, as measured:				
Heat of urine and feces given off	17	.8	21	.4
Given off by radiation and convection	1,741	76.7	3,856	74.0
Given off by vaporization of water	512	22.5	791	15.2
External muscular work measured	....	....	546	10.4
Total heat given off	2,270	100.0	5,214	100.0

In the foregoing experiments the temperature of the chamber occupied by the subjects experimented on was 20 deg. C., and the humidity of the contained air ranged mostly from about 50 to 70, averaging 67 per cent.

The cutaneous surface and the respiratory tract are the structures chiefly concerned in the elimination of heat. The body surface affords an extensive field from which heat may escape by radiation, conduction, and convection, and from which the evaporation of perspiration takes place. The respiratory activities involve vaporization of water and convection of heat out of the body by the warm expired air. A striking example of the participation of the respiratory apparatus in heat elimination is afforded by an overheated dog breathing with excessive rapidity; the widely opened mouth and expanded tongue increase the surface for heat discharge, and the increased air currents carry away much heat by convection and augmented evaporation.

In infancy the burden of heat elimination is relatively much greater and more urgent than in adults. Heat production in young infants proportionately to body weight is three times as great under similar conditions as in adults; a proportion which gradually diminishes during the years of childhood. The much greater amount of heat to be disposed of in them makes interference with their heat elimination much more potent for harm than in adults, and undoubtedly contributes largely to the increased morbidity and mortality of young children in hot weather.

Obesity exerts considerable influence on heat elimination. An abundance of subcutaneous fat, by relatively diminishing the body surface and interfering with radiation-convection and evaporation, lessens heat dissipation. Their heat discharge is so much more interfered with that obese persons suffer more distress in hot and humid weather than slender subjects experience.

The principal external conditions that influence heat elimination are (1) the clothing, (2) the tem-

*Read before joint meeting of the Baltimore City Medical Society and the Medical Society of the District of Columbia at Baltimore, Md., April 7, 1916.

perature of the surrounding air or other media, (3) the humidity of the atmosphere, and (4) the movement of the air.

Clothing protects against and lessens the escape of body heat, and by varying its amount and character a considerable range of control and adjustment of heat elimination is possible. The physiologic action of clothing pertains largely to its influence on heat elimination. Clothing (like the hair and feather covering of animals and birds) owes its protective power against heat loss largely to the air imprisoned in its interstices, air being a poor conductor of heat. Dry, porous clothing is the best protection against cold. Water being a good conductor, damp clothing facilitates loss of body heat, and is less protective.

The temperature of the surrounding atmosphere and other objects or media influences heat elimination by both radiation-convection and evaporation.

The greater the difference in temperature between a body and the surrounding media, the more active is the transfer of heat from the warmer to the cooler. Consequently, the body gives off more heat in a cold than in a warm environment; and as the surrounding temperature rises, the heat loss by radiation-convection correspondingly diminishes. When the temperature of the air becomes as high as that of the body no further loss of heat by radiation-convection can take place.

Immersion in cold water actively removes heat from the body; and one of the chief effects of hydrotherapy relates to this action.

The effect of atmospheric temperature on the vaporization of water is the reverse of that on radiation-convection. At the lower temperatures there is less evaporation, and hence less heat loss in that way; while at higher temperatures vaporization and the resultant heat loss are proportionately increased.

As an example of the effect of varying temperatures on the distribution of heat loss between radiation-convection and evaporation may be cited the following results obtained by Rubner on the elimination of heat by a fasting dog exposed to different temperatures (Max Rubner, *Die Gesetze des Energieverbrauchs bei der Ernährung*, 1902, pp. 106, 193):

Table II

Temperature	Total Heat Given Off per Kilo of Body Weight	Heat Given Off By Radiation-Convection		Heat Given Off by Vaporization of Water	
C.	Calories.	Calories.	Per Cent.	Calories.	Per Cent.
7°	86.4	78.5	90.9	7.9	9.1
15	63.0	55.3	87.8	7.7	12.2
20	55.9	45.3	81.0	10.6	19.0
25	54.2	41.0	75.6	13.2	24.4
30	56.2	33.2	59.1	23.0	40.9
35	68.5	.....	.....	.....	.....

The humidity of the atmosphere influences the escape of body heat mainly through affecting the evaporation of water. In dry air, vaporization is favored; in humid air, evaporation is lessened; while in air saturated with moisture, escape of body heat by evaporation would be entirely prevented. A cold, humid atmosphere also favors heat loss, supposedly by the increased conductivity for heat of damp clothing or skin covering.

Movement of the surrounding air, even imperceptible air currents, greatly increase loss of heat from the body. The air envelope contiguous to the body, warmed by its heat and charged with its moisture, is thus continuously removed and replaced by cooler and drier air of greater heat-absorbing capacity.

Variations in the rate of heat elimination resulting from fluctuations in the external conditions and factors operative bring about through the action of the thermic nerve centers a series of compensatory and regulatory processes for the purpose of maintaining proper thermic conditions in the body, one significant manifestation of which is the maintenance of a uniform body temperature. The train of vital activities thus brought into play covers a wide field of the organic functions, and is of profound consequence to the organism for evil or for good. Within broad limits, the organism can accommodate itself to the variations in heat dissipation brought about by changes in the external conditions. Above and below these limits, pathologic consequences result, ranging from mere discomfort in the slighter degrees to fatal and fulminant overwhelming of the organism. Two opposite groups of conditions are to be considered, resulting respectively from (1) excess or (2) deficiency in body-heat elimination.

Excessive abstraction of body heat is brought about by insufficient clothing, immersion in cold water, exposure to cold air, and similar conditions. In order to check the excessive escape of heat, contraction of the superficial blood vessels takes place under the action of the nervous regulatory mechanism, blanching the skin and lessening the amount of blood at the surface, thus diminishing the radiation and convection of heat from the skin, the action of the sweat glands, and the consequent evaporation of water. The pulse and respiration rates decrease. Blood pressure increases, perhaps as a result of the contraction of the cutaneous vessels. The largest means of compensation for the excessive heat loss is the incitement of muscular activity, which greatly augments body oxidation and production of heat to replace that lost. The cold individual naturally and spontaneously engages in muscular action; he stamps his feet, or swings his arms, or otherwise actively exercises. In the passive, chilled, individual shivering or twitching of the voluntary muscles is a similar means by which heat production is increased.

The reaction of the organism to increased heat elimination involves powerful stimulating effects. The circulatory activities are stimulated, as shown by the increase of blood pressure. An increase in blood pressure of 10 to 30 mm. can be effected by transfer of patients and individuals from warm rooms to cold outdoor air, a stimulating effect much greater than drugs produce. The nervous system is markedly stimulated, partly from the direct action of cold on the superficial nerve terminals, partly perhaps from increased central circulation. Muscular activity is promoted. Metabolism is increased. General invigoration takes place. The purposive induction of these stimulating factors constitutes a powerful therapeutic agency.

When, in spite of all regulatory and compensatory reactions, the loss of heat exceeds the generation of body heat, the temperature of the body must progressively fall, leading eventually to fatal refrigeration. The treatment of such cases would consist in the promotion of muscular action, the application of external heat, hot drinks, and the like.

Decrease or deficiency of elimination of body heat is caused by high surrounding temperature, high atmospheric humidity, lack of movement of the air, and excessive clothing; and the conditions are relatively much aggravated when associated with muscular activity and increased heat production. When heat elimination is interfered with the thermo-regulating centers set up conditions to increase it. The superficial blood vessels dilate, bringing an increased volume of blood to the surface, where its heat can be dissipated by radiation and convection. The skin is flushed and warmed, and the secretion of sweat is greatly stimulated to supply water for evaporation. Blood pressure is lowered (perhaps from the dilatation of the vascular channels), and the pulse rate increases. The rate of respiration is increased, partly perhaps in correspondence with the pulse rate, partly also as a means for increasing heat discharge. Marked nervous depression occurs (partly perhaps from relative central anemia), as manifested by lassitude, malaise, weakness, headache, dizziness, nausea, faintness, syncope. Muscular activity is burdensome, on account of the great increase thereby effected in the production of heat to be gotten rid of. There is general depression and embarrassment of the body functions and activities. The proper action of the cooling apparatus is just as essential to the efficient working of the human machine as to that of an automobile; neither will run properly if overwarm.

When the rate of heat dissipation falls below that of heat production the body temperature must necessarily rise and pyrexia develop. These are the conditions that bring about the most intense manifestation of deficient heat elimination—heat stroke. With the atmosphere at a temperature as high as that of the body, and saturated with moisture, the escape of body heat by both radiation and evaporation would be entirely prevented, and the body temperature would rise at a rate of over 3° F. per hour, the rate of increase being accelerated by the increase of oxidation accompanying overwarming of the body cells. The concurrence of heat and humidity, especially if associated with muscular activity, is well known as the special inciting cause of heat-stroke, with its rapidly induced hyperpyrexia (up to 110° or 112°) and fulminant overthrow of the vital activities.

Body oxidation, or metabolism, runs closely parallel with heat elimination, as the abstraction of heat necessitates oxidation (under the control of the thermic centers) to produce heat to replace that lost. As heat dissipation is largely conditioned by the external temperature, there is a close correspondence between the surrounding temperature and body oxidation. External cold greatly increases body oxidation; metabolism decreases as the temperature rises, reaching a minimum at about 30° C., above which oxidation again increases (attributed to heightened metabolic activity of overwarmed cells). The influence of cold in increasing oxidation is to a certain extent independent of muscular activity, and affords a sanitary or therapeutic means of stimulating metabolism in cases in which exercise is inadvisable or impossible.

A potent influence is exerted by these conditions on the bodily vigor and disease-resisting power. The increase of morbidity and mortality, especially among children, in seasons of atmospheric heat and humidity, is well known. Continued exposure to the conditions that diminish heat elimination evidently lessens the power of disease resistance. On the other hand, the conditions that increase heat dissipation and metabolism are associated with heightened vigor, health, and recuperative power, as exemplified in the difference between sedentary and outdoor life, the energizing effects of open-air life and treatment, etc. It is a reasonable supposition that the basis of this relation and correspondence between heat elimination and body vigor is to be found in the amount of body oxidation, which is conditioned on the former. Oxidation is life. All vital energy and activity are derived from the combustion of organic material. The more we oxidize the greater is our activity and vitality, the more we live. The conditions that diminish body oxidation lessen vigor and disease-resistance; those that stimulate metabolism energize the organism and tend to the conservation of health and the cure of disease; and this applies to passive increase of metabolism caused simply by exposure to cold as well as to increase caused by muscular activity.

A familiar manifestation of deficient heat elimination is afforded by the oppressive and injurious consequences of hot and humid weather. The depression, the malaise, discomfort, and distress, and the difficulty of muscular exertion under such circumstances, are universal experiences; but of great concern to the clinician is the fact that these conditions materially increase susceptibility to the incidence of various diseases, aggravate their character, lower disease-resisting power, and increase the mortality, especially in young children. Purposive measures to promote adequate heat elimination should, consequently, constitute an important part in the prophylaxis and treatment of disease in hot seasons.

The discomfort and other injurious conditions that result from exposure to the vitiated air of stuffy, crowded, or badly ventilated rooms, is another manifestation of the effects of reduced heat elimination. The belief, long prevalent, that the evil effects of vitiated air are caused by chemical changes and contaminations has been found untenable; and it is now believed that it is interference with body-heat elimination caused by the increased temperature, humidity, and stagnation that also develop in occupied confined air that is responsible for these evil effects. The cooling action of the atmosphere is vitally essential to well-being and life, as well as its respiratory function; and it is the air that cools us, rather than the air we breathe, cool air rather than pure air, that is most concerned in ventilation and aerotherapy.

The treatment of deficient heat elimination and its resultant conditions would consist in abstraction of body heat, increasing the outlets for heat discharge, and minimizing body oxidation.

The most vigorous abstraction of body heat is effected by immersion in cold water, application of ice, and the like, as in the customary treatment of heatstroke and fever.

A slight cooling may be effected by the ingestion of cold substances. A glass of water (250 c. c.), swallowed at zero temperature (Centigrade), when warmed up to body temperature will absorb about 9 calories of heat, enough, if generally distributed, to lower the body temperature about 0.3° F. A hundred grams of ice (as in ice cream), swallowed, melted, and raised to body temperature, would absorb nearly 12 calories. The gains thus obtainable are perhaps inconsiderable, yet they afford an agreeable sense of cooling.

When the conditions are such as to interfere with

heat elimination, it is important that body oxidation (and hence the amount of heat to be gotten rid of) be reduced to a minimum. Muscular activity should, therefore, be minimized; and, theoretically at least, a scanty diet (especially of protein) would be advisable, in order to obviate the increase of oxidation involved in the specific dynamic action of the foodstuffs.

Since clothing lessens the escape of heat, reduction, and even complete removal, of the body coverings may effect a considerable increase in heat discharge, and should be borne in mind in alleviating the injurious effects of hot weather on ill patients, especially children.

Atmospheric conditions that interfere with heat elimination should be escaped from or corrected so far as possible.

The preferable and most effective course, when possible, is removal from hot cities or torrid localities to cooler places during heated seasons. The beneficial effects of such a change for invalids, children, and also the well, are generally appreciated.

When it is impracticable for the patient or individual to remove to a more salubrious place, the oppressive atmospheric conditions of the room occupied should be mitigated so far as possible. Great and frequently sufficient relief may be obtained by setting up vigorous air currents in the room with fans. Reduction of the temperature of the room air is not so easily accomplished. Methods have been devised for lowering room temperature through the agency of evaporation, and cooling beds with ice tanks. It is feasible, though expensive, to cool the air supply of buildings by refrigerating apparatus, humidity being also regulated; but such systems have been put in operation only to a limited extent. It is possible that the equipment of wards or rooms in hospitals capable of being refrigerated, in which very ill patients could, as an emergency measure, be placed in hot weather, would result in the saving of many lives, especially of children.

According to present conceptions, the primary purpose of the ventilation of buildings is the regulation of the temperature, humidity, and movement of the air, so as to provide optimum conditions for the heat excretion of the occupants. In the attainment of this essential object, with the exclusion of dust and of adventitious contaminations, a sufficient degree of air purity is likely to be incidentally achieved in ventilating systems. In ordinary places of residence and assembly, where physical activity is slight, a temperature of 68° to 70° F., with a humidity of 60-65 per cent., affords favorable conditions for body heat elimination; in industrial establishments where workmen are subjected to heavy exertion or high temperatures other arrangements would be indicated. In many dwellings, in winter, the temperature is kept too high, resulting in deleterious overwarming of the occupants. The matter of ventilation and heating is an important aspect of this subject, well worthy the attention of the sanitarian and therapeutist.

The therapeutic bearings of heat elimination relate not only to the removal of the injurious consequences of deficient elimination, but also to the utilization of the great therapeutic potencies of increased heat removal. Amplified heat elimination is a powerful circulatory, nervous, and metabolic stimulant, promotes muscular activity, and is generally energizing and invigorating. Our daily vigor, well-being, and efficiency are dependent on it, as is shown by the debilitating effects of hot weather and of sedentary indoor life as compared with the invigorating influence of outdoor life. The brilliant results of the open-air treatment of tuberculosis and other conditions are a demonstration of the therapeutic possibilities involved. The attempted explanations of the modus operandi of the fresh-air treatment on the basis of the chemical purity and properties of the air have never been convincing, and undoubtedly the true cause of the beneficial action of salubrious atmospheric conditions resides in their influence on the heat discharge of the body.

In general, the elimination of body heat, far from being an academic physiologic abstraction, is a process of fundamental importance to organic well-being, and has wide pathologic, therapeutic, and hygienic bearings. Without being directly appreciated, it sets up a train of vital phenomena that are very obvious and consequential. It affords a key to the understanding of subjects formerly obscure. It is well that its action and controlling factors should be clearly appreciated and purposely regulated or utilized.

1321 Rhode Island Avenue, N. W.

COINS AND MEDALS IN MEDICINE*

By WILLIAM J. MALLORY, A.M., M.D.,

WASHINGTON, D. C.

INSTRUCTOR IN MEDICINE IN THE GEORGE WASHINGTON UNIVERSITY, DEPARTMENT OF MEDICINE, AND ATTENDING PHYSICIAN TO THE OUTPATIENT DEPARTMENT OF THE UNIVERSITY HOSPITAL.

Ancient history deals almost exclusively with affairs of State and gives us comparatively little insight into individual experience of its members, their joys and cares, pleasures and privations, how they dealt their "buried complexes" or adapted themselves to the "kinetic drive" of their day.

In an attempt to fill in deficiencies and make a complete and authentic story, the historian has drawn from many different sources of information, among others, numismatics.

The study of coins, medals, and jetons adds many facts to history, not only as a memorial of important events, but they furnish also likenesses of persons, as well as parts of legends and proverbs. As an example may be mentioned our own penny, with its inscription of "Not one cent for tribute, but millions for defense," or the Franklin penny, with "Time flies; mind your own business."

The material available for a study of coins and medals in medicine is enormous in amount and variety, and may be found in books and papers, as well as in collections which have not yet been studied and described. There is in the Museum of the Surgeon General's Library a rich and attractive collection of coins and medals waiting to be described and discussed from this point of view.

In this brief sketch an attempt will be made simply to call attention to some well-known coins and medals of interest to physicians, and to name some of the many interesting books dealing with this subject.

As an example illustrating the kind of information which may be derived from medals, Weber[1] mentions the one relating to Dr. Wenzel Beyer. He was the author of the first treatise on the thermal waters of Karlsbad in Bohemia. Being practically the first to recommend patients to take the waters internally, he must have enormously increased their utility. In this book above referred to, "Tractatus de thermis, Caroli IV, Etc.," Leip-

*Read before the Medical History Club of Washington, D. C., Jan. 29, 1916.

zig, 1521, he wrote: "I have said that this water must be drunk. As, however, until now it has seldom been used for drinking, but more for bathing, what I have said will appear to many as something new."

Beyer was born at Elbogen near Karlsbad, as appears from the title page of his book, where his name is given as Venceslaus Payer de Cubito, that is to say, of Elbogen. Not much more would be known or surmised about Beyer were it not for the existence of two medals commemorating his death in 1526, examples of both of which exist in the Imperial Collection at Vienna. Like most German portriat medals of this time, they are doubtless the work of some goldsmith and are both cast and chased in silver.

The first one, of a diameter of 2.2 inches, bears on the obverse the portrait of Beyer, in profile to left, at the age of 38 years, with an inscription. On the reverse, in a bare landscape with one tree, is a steaming chasm, into which a horseman (Marcus Curtius) is about to plunge. In the foreground is a book, and upon that rests a skull; there are loose bones lying about, and in some specimens the date 1526 occurs in the field. The inscription is "Iam portum inveni, spes et fortuna valete." The more usual quotation is "Inveni portum; spes et fortuna valete! Sat me lusistis, ludite nunc alois." That is to say, "I have found the haven; Hope and Fortune, farewell. You have made sport enough of me, now make sport of others." It is said to be the translation of a Greek epitaph ascribed to Janus Panonius. The reverse type certainly suggests a reference to Marcus Curtius, the Roman legendary hero, who, when he heard that the chasm in the Forum could be filled only by throwing Rome's greatest treasure into it, mounted his horse and leaped into the abyss, declaring that Rome possessed no greater treasure than a brave and gallant citizen.

The second medal, two inches in diameter, bears Beyer's bust on the obverse, with a similar inscription to that on the obverse of the first medal, but the portrait is nearly a full-face one. The reverse represents a bier, standing on stony ground, with a decaying corpse stretched at full length upon it. Above this is the inscription: "Cum pariter Omnibus moriendum non tarde sed clare mori optandum."—"Since all alike must die, it is desirable to die not tardily, but illustrously." On the field of the reserve is the date, 1526.

Nothing seems to be known with certainty as to the cause of Beyer's death, but the reverse designs on these two medals, especially that referring to the legend of Marcus Curtius, suggest that his death was the result of (or at the time supposed to be the result of) an injury or disease acquired when examining the source of the great hot spring (Sprudel) at Karlsbad.

At the present day, close to this spring along the sides of the River Tepl, clouds of steam arise from the ground itself. The rocky ground on which the bier stands (in the second medal) probably represents the bed of the Tepl, and the book (on the first medal) is probably an allusion to Beyer's book on the Karlsbad Springs.

Beyer's patron, Count Stephan Schlick, to whom he dedicated the treatise in question, was hereditary lord of Elbogen and doubtless owned Karlsbad itself; therefore, Beyer's book, by increasing the use of the thermal waters, was probably of some financial service to the Schlick family, who apparently had these commemorative medals made. They are, as already stated, made in the ordinary manner of the period, that is to say, cast and chased, probably the work of some goldsmith patronized by the Schlick family. Count Stephan Schlick himself was one of those who perished with their sovereign, King Louis II of Hungary (and Bohemia), in the disastrous battle against the Turks (under Soliman II) at Mohacs on Aug. 29, 1526.

It was by this Count Stephan Schlick and his brothers that the large silver coins were issued at Joachimsthal, called Joachimsthaler, from which the words thaler, daler, and dollar are derived.

The correct explanation of the types on these medals is chiefly due to J. de Corro, who wrote an account of them in a Karlsbad Almanac published in Prague in 1841.

There are some Greek coins of the fifth century B. C. illustrating a medical and hygienic attitude towards preventable disease and death. Two silver coins of Selinus in Sicily date from about 466-415 B. C., and commemorate the freeing of Selinus from some kind of pestilence, probably malaria, by the drainage of the neighboring marshlands. One shows on the obverse Apollo and Artemis standing side by side in a slowly moving quadriga, the former discharging arrows from his bow. On the reverse is represented the river god Selinus, naked, with short horns, holding patera and lustral branch, sacrificing at an altar of Aesculapius, in front of which is a cock. Behind him on a pedestal is the figure of a bull, and in the field above is a selinon leaf. Apollo is here regarded as the healing god who, with his radiant arrows, slays the pestilence as he slew the Python.

On the reverse the river god himself makes formal libation to the god of health, in gratitude for the cleansing of the waters whilst the image of the bull symbolizes the sacrifice offered on that occasion.

The other of these two coins shows on the obverse side Heracles contending with a wild bull, which he seizes by the horn and is about to slay with his club. On the reverse the river god Hypsas is seen sacrificing before an altar, around which a serpent twines. He holds a branch and a patera. Behind him a marsh bird is seen departing. In the field is a selinon leaf.

It is said of this piece that here, instead of Apollo, it is the sun god Herakles, who is shown struggling with the destructive powers of moisture symbolized by the bull, while on the reverse the river Hypsas takes the place of the river Selinus. The marsh bird is seen retreating, for she can no longer find a congenial home on the banks of the Hypsas, now that Empedocles has drained the lands.

It seems that the philosopher Empedocles, who at that time was at the height of his fame, put a stop to the plague by turning two neighboring streams into one. The Seluntines conferred divine honor upon Empedocles, and these above-described coins still exist as a wonderful monumental record of the events in question.

The study of coins and medals adds something to our incomplete knowledge of the early epidemics, not only with regard to dates and places, but also gives hints of what was at that time believed with regard to the nature, cause, and methods of preventing epidemic diseases.

However, it is only since the sixteenth century that the knowledge of the varied nature of epi-

demics were "pests" or "plagues." Smallpox was described by a few physicians in the eleventh and twelfth centuries, but became generally known only in the sixteenth century. Scarlet fever and measles were differentiated from smallpox in the sixteenth century, but not from each other till 1627. In 1700 the difference became generally known, and in 1790 was entered in the official statistics.

Bubonic plague was not known as a specific disease in the Middle Ages. Only the particular form known as the "black death" was accurately described and characterized by its incomparable mortality.

Typhus has been known since 1584; malaria was known as a specific disease in 1600; yellow fever in 1635.

As examples of Roman coins[3] alluding to disease, may be mentioned several gold, silver, and bronze pieces of about A. D. 250-254, having on one side the head of the emperor, with his name and title around the margin, and on the opposite side Apollo standing with a laurel branch in the extended right hand, and inscribed about the margin, "Apollo. Salutari."

These pieces are considered to have been struck under Valerian, and seem to refer to the so-called "Cyprianic Pest," which was brought out of Ethiopia in the time of the Emperors Hostilianus and Trajanus Decius, numbering the son of the latter among its victims. The character of this pest is uncertain, but according to the writings of St. Cyprianus, it resembles exanthematic typhus with diarrhea. Of the next plague, the "Pest of Justinian," 531-580, buboes and petechiæ are expressly mentioned. Contemporaneous coins bear no mark referring to this epidemic.

Of the second and most severe outbreak of epidemics of oriental bubonic plague there is no numismatic memorial. It is said that during that grievous period of the "Black Death," 1346, till near the end of that century the coining of moneys was, as in the whole Middle Ages afterward, limited to immediate necessities of commerce and daily traffic. Only after 1390 appeared some memorial medals. Even after this time some of the most important epidemics passed without leaving behind any reminders on the coins. Perhaps many of the skilled artists were the victims of the plague. Perhaps the misery and depression were so great and universal that no one had the zest or desire to make any such souvenir.

In later years, that is in the 16th century, coins bearing some reference to plagues become more numerous. The "Wittenberger Pest-thalers" furnish a good example of the period. They consist essentially of a representation of Christ on the cross, a marginal biblical quotation, at the foot of the cross, worshippers, and on the opposite side the prototype—the serpent as lifted up on the cross by Moses in the Wilderness. Here also is the appropriate scriptural quotation. The distinct biblical motive in these pieces indicate that they were not mysteriously working amulets, but pious faith tokens. In striking contrast to these were "Pestpfennigs," which appeared in South Germany about a hundred years later. Instead of the scriptural figures appear wonder-working saints—Benedict and Zacharia with their spells and exorcisms, "Get behind me, Satan," "Drink the poison yourself," etc. Here we have a transition, or a relapse, to the amulet and talisman against disease and other evils, which still persist in our present day as good-luck pennies.

Coins and medals relating to smallpox and inoculation are numerous, but do not appear till after the practice had become established. Although something of the relation between cowpox and human smallpox had been known for years, and Lady Montague, as early as 1717, had caused her son to be successfully inoculated and in 1720 introduced the practice in England.

The first medal that I have found record of as relating to this subject were struck in 1756. This was ordered by the Count Tessin in honor of his wife, who introduced the practice into Sweden by having her children inoculated. Medals were also issued in nearly every European country in honor of Jenner and others who practiced inoculation.

There are medals referring to cholera, some commemorating the appearance of Asiatic cholera in certain cities, as, for example, one with the inscription:

"Berlin von der Asia. Cholera Enricht, D. 31, Aug., 1831—

(Humble yourselves now under the mighty hand of God.")

"Demutiget Euch Nun Unter Die Gewaltige Hand Gottes."

And another by the citizens of Goldigen "in memory of Dr. Kupffer and Rv. Schmidt, helpers in need."

There were numerous amulets to be worn for protection against disease. One appeared in Munich in 1836, bearing on one side the inscription: "This medal is to be worn in region of the stomach next to the skin."

The history of the touch pieces,[4] that is, coins used in connection with the ceremony of touching for the cure of *King's Evil*, forms one of the most interesting chapters in the history of medical numismatics. King's healing of the Evil probably began with the first king; for just as disease was attributed to evil spirits, so has healing in all times and nations been accorded a divine parentage; and since kings ruled by divine right, their powers were divine, so, logically, healing was early included among other attributes of sovereignty. Phyrrus, king of Epirus, in the early part of the third century B. C., cured disease of the spleen by the touch of the patient with the great toe of his right foot. Vespasian restored sight to a blind man, and Adrian cured the dropsy by the touch of his finger tips.

Coins were first used not directly as touch pieces, but as alms, when King Guntran, during the plague in Marseilles, gathered the people into the churches and bade them offer prayers, vigil and fasting, while he himself distributed his alms broadcast, and apparently the plague was stayed.

The first reliable record in French or English history of healing by royal hands is four centuries later, when Robert the Pious (996-1031), who gave each of the sick folk with his own hand a sum of pence, touched their sores, and made the imprint of the sign of the holy cross. The household accounts of Edward I show numerous entries of monies disbursed to persons sick of the King's Evil —a pence per head.

The circumstances under which a certain coin—The Angel—became definitely associated with healing by the royal touch, are very interesting. Crawford credits Henry VII with being the first to initiate the practice of giving to each applicant a golden Angel, a current coin of the value 6s. 8d. After a century of comparative neglect it was he who restored the currency to its original dignity. With

no just title to the throne by descent, and too proud to accept the crown as a mere king consort, Henry spared no pains to fortify his position by other means. To throw lustre on himself as a scion of the house of Lancaster, he even sought to canonize the pious imbecility of his Lancastrian predecessor Henry VI. The requisite miracles were forthcoming, wrought at his shrine, but it is said that in addition to other difficulties Henry's thrifty soul shrank from the expenditure of 1500 gold ducats, the least amount that would satisfy the legitimate expectations of a horde of greedy menials on so important an occasion. Thus minded, it is no matter for surprise that he should have desired to popularize a ceremonial which, in the eyes of the common people at least, stamped him as being the Lord's annointed.

It is important to consider briefly the origin of the Angel, because in spite of the generally accepted tradition, it suggests the possibility that its bestowal on the sick may have been initiated by Edward IV and merely revived by Henry VII.

The Angel was first ordered to be struck by Edward IV in 1465 A. D., but it does not seem to have been absolutely minted until 1470. Its name, "Angel," is derived from the figure, on the obverse, of the Archangel Michael piercing the dragon, surrounded by the words "Edward, Dei Gra. Rx. Angl. Et Franc." On the reverse was a ship with masts in the form of a cross surmounted by sunrays and surrounded by the legend: "By thy Cross save us Redeemer Christ." This is the first appearance of this legend on the coinage, and suggests an association with the ceremony of healing. There is, however, nothing to confirm this conjecture in the original warrant for its minting. Henry VI, during his brief restoration, 1470-1471 A. D., Edward V, and Richard III, all issued an almost identical Angel. On succeeding to the throne, Henry VII in his first issue of 1485 A. D., retained the same Angel with the essential modifications, but also issued an alternative form, bearing the legend: "And the angel said unto her, Fear not, Mary, for thou hast found favor with God," taken from the Noble of Edward III, which was much used as an amulet in battle. The double issue shows that from the commencement of his reign Henry VII proposed using the Angel in the ceremony of healing and considered the legend selectd by Edward IV appropriate for such a use. In 1489 he issued a second Angel with trifling variations and again with the same alternative legends.

The quaint old herbalist of later days, Nicolas Culpeper, has a jibe at physicians anent the Angel, that, like Balaam's ass, they will not speak till they have seen an "Angel"—an habitual fee.

James I seems to have been the first sovereign to have Angels specially minted for healing in addition to those to be circulated as current coin.

A document in the Public Record Office dated April 10, 1611, is a warrant to the Treasurer and Under Treasurer of the Exchequer, and shows that healing Angels were specially minted to his order. The omission of the cross from the ship's masthead and also a part of the inscription, is said to indicate the sceptical trend of his mind. Charles I used Angels specially minted for the purpose. These Angels bore the legend, "The love of his people is the King's safeguard." After 1634 no more Angels were minted.

Medalets were also used as touch pieces, for there is in the British Museum a bronze medalet about the size of the touch piece of Charles II. It has on the obverse a hand stretched out over four human heads, with the words "He touched them," and on the reverse a rose and thistle under a crown, with the words "And they were healed." And in the accounts of the Wardens of the Exchange and moneys within the Tower 1625-1642, there is to be found under date of 1635-6, Allowance of a payment to the chief graver for making token for the healing of the King's Evil, and delivered to William Clowes, Sergeant Chirurgeon at 2d the piece: these numbering 5500.

It is said that with the accession of the house of Hanover, the ceremony of healing, as a prerogative of the Sovereign, died a natural death in England, George I having declined to touch a sick child, but the touch pieces continued to be used, being passed from patient to patient.

In France healing by royal touch was practiced by Charles X, who revived the whole ancient ceremonial at his coronation in 1824. But who shall say the custom has entirely passed away? There is at least one good old physician in an Eastern city who, after prescribing for his patient, sometimes remarks that he, during his summer vacation, visited a famous shrine in Canada—he brought back with him some interesting little medals—would the patient like to have one—"Take it, then, perhaps it will help you!"

GENERAL PRINCIPLES TO BE OBSERVED IN BONE TRANSPLANTATIONS.

By CLARENCE A McWILLIAMS, M.D., F.A.C.S.,
NEW YORK.

1. Most scrupulous asepsis is an absolute essential to perfect success. To assure with the greatest certainty that no infection be introduced into a clean field at the time the graft is transplanted, the operator, assistants, and nurses should all wear rubber gloves and the same scrupulous Lane technique should be employed as in operating on fractures, i.e., nothing that has been touched by the hand should go into the wound or touch the graft and all instruments and gauze wipes should be handled by instruments alone. It is advisable not to tie vessels but to allow the artery forceps to remain hanging in situ during the operation, after which they can be removed with little danger of bleeding. All sutures should be tied by means of clamps to avoid touching the suture with the hands. Instruments once used should be laid aside and reboiled before using again. Sterile towels should be clamped all about the edges of the wounds so as to exclude the skin from the operative field. All this applies both to the site of the graft as well as to the field from which the graft is removed. A new knife should be used after the skin is incised and the old one should be laid aside. Tincture of iodine

may be applied to the cut skin edges immediately after incision.

2. In general it may be said that all sinuses should be perfectly healed for two or three weeks before grafting is attempted so as to prevent infection of the graft. While infection does not necessarily mean the death of the whole graft, yet the danger that it may entirely die is very great. Lewis has demonstrated in two cases that a transplant may be inserted into an infected area with the object of acting merely as a mechanical support to prevent deformity, even if it is necessary to remove it later. In some instances such grafts may remain viable and hasten convalescence.

3. The graft should be taken living from the same individual who is to receive the graft (*i. e.* an autoplastic or autogenous graft), if the best and surest means for success are followed. If this be not possible, which is very rare, then it should be taken from as near a blood relative as possible. Animal bone should never be used, because such a graft will be absorbed, owing to the changed serological and chemical relations. If taken from another individual, syphilis should be ruled out by the Wassermann reaction, as well as tuberculosis should be excluded.

4. A living graft should be transplanted *always* with as much periosteum covering it as possible. *Without* the periosteum the life of a graft has proved to be uncertain. Its retention will insure success if asepsis be attained and immobilization maintained. The question of just what the function of the periosteum is is an academic one. Practically the periosteum seems necessary for success in the greatest number of cases. Less important for success but still advantageous is to have endosteum also on the graft, for the whole of a thing is greater than any of its parts. The value of marrow seems to be small; according to some authorities, it is disadvantageous.

5. The success of a graft seems to depend upon a speedy adherence of the periosteum to the surrounding parts that the blood supply may be as quickly established as possible. Effused blood will prevent this adhesion, hence bleeding and oozing should be checked to the greatest extent possible. In addition a blood-clot about a transplant does not permit of a permeation of serum into the bone and also prevents vascularization. Lewis gives several instances in which hematomata caused absorption after graftings. On account of the subsequent oozing a tourniquet had better not be employed.

6. No drain should be used, since this predisposes to infection.

7. A motor saw is of inestimable value in bone-grafting operations. The best is Albee's motor saw made by the Kny-Scheerer Co., New York.

8. In taking a graft from the tibia, its crest should not be employed, for this is the strongest part of the bone and its removal will predispose to subsequent fracture. Before this was appreciated, McWilliams had two fractures of the tibia from whose crests grafts had been taken, while other fractures have been reported, thus, Dyas reports such a fracture, also Rhodes, while Morris reports two cases. At a recent meeting of the American Roentgen Ray Society six cases were shown of fractures of the tibiæ following the removal of bone for transplantation. If the crest is used the limb should be strengthened by a plaster splint for several months after the transplantation, as new bone in such a defect is but slowly reformed.

9. All foreign non-absorbable material, wires, nails, celluloid, horn, rubber, etc., should be avoided as implants unless under very exceptional conditions. Encircling wires will erode the bone and a fracture will result. These non-absorbable foreign bodies tend to irritate, if not invite suppuration, and often produce sinuses which will usually require their removal to cure such sinuses. Chromic gut or kangaroo tendon should be used to fix the graft in position.

10. When the head of the humerus, or radius, or femur is fractured and dislocated and the joint is opened, then the head should be replaced and attached to the freshened lower fractured surface, even though the head be dead, provided it is still aseptic.

11. A graft increases in size according to the demands put upon it by the organism. Experience has taught that it is unnecessary to laterally fill up a defect completely with a graft. It is essential to fill up a defect vertically, leaving to nature to do the remainder.

12. After transplantation absolute immobilization is essential for success. This should be maintained for at least three or four months, or longer if roentgenograms show its necessity.

13. The periosteum of the bone into which the graft is inserted is an important element and should be preserved and brought into contact with the periosteum of the graft or over the ends of the same, if possible.

14. The inlay graft in the treatment of fractures is to be preferred theoretically to the intramedullary splint, since endosteum comes in contact with endosteum while the periosteum of the graft can be sutured to the periosteum of the bone. A much more successful method of treating non-union in fractures than a Lane plate is the bone graft. The intramedullary splinting has, however, given good results in the hands of many surgeons, particularly Murphy.

15. Transplantation of long bones with their joint surfaces has been successfully performed, as has been the case with half joints and with whole joints in a few instances. In most instances, however, the transplantation of joints has not been better in results than those accomplished by resections.

16. A suggestion by Huntington seems valuable. He has found that the periosteum of a graft may be preserved in situ during operation by wrapping the fragment closely with zero catgut. Before closing the wound the strands of gut are divided and removed or cut short.

17. In operating on comminuted fractures, whether simple or compound, replace the fragments, if possible, in their original positions. If this be not possible, fragment the pieces, retaining all the periosteum possible on the fragments and replace them about the fracture spot.

18. The site from which a free graft may be obtained seems to depend upon the individual preference of the surgeon. The majority seem to have used the tibia, while the fibula has been preferred by fewer others. In a few instances grafts have been taken from ribs, clavicle, scapula, crest of the ilium, and bones of the hands and feet.

19. Do not transplant a graft into the midst of dense connective tissue, since the nourishment of the graft will suffer. Excise the connective tissue and check the bleeding by packing before inserting the graft.

20. The bed into which the graft is to be trans-

planted should be prepared first. Then the graft is obtained and placed in its new bed just as quickly as possible that its cells may not suffer from lack of nourishment for any longer period than is absolutely necessary to make the transfer. In order that blood and serum contained in the graft be not washed away, theoretically it were more scientific not to immerse the graft in salt solution, but to wrap it in gauze wet in salt solution if there is to be any delay in its transfer. This will prevent the drying out of the graft by evaporation.

STATE MEDICAL SERVICE AS CONTRASTED WITH THE PANEL SYSTEM FOR THE CARE OF INDUSTRIAL WORKERS.

By A. C. BURNHAM, M.D.,

NEW YORK.

When a popular English dramatist, writing a decade ago, prophesied the State control of medical care for the individual, his statements were made the butt of many derisive remarks and, as it happened, the comments of the medical profession were the most bitter.

It is a well-recognized fact that the physician is a member of one of the most, if not the most, conservative of professions. Only a short résumé of medical history convinces one that in the medical profession there is an overdeveloped sense of conservatism, not to say obstinacy, which makes its appearance upon the introduction of radically different methods of treatment and new social developments. From a medical point of view this is perhaps right and proper, for it is only by this spirit of conservatism that useless, and in many cases harmful, methods of treatment are kept within reasonable limits, and the exploitation of the public by means of spurious "cures" is made more difficult. If in this process the advancement of medical science is somewhat delayed the final results are probably beneficial.

In respect to the socialization of medical service, however, the situation has been handled much less satisfactorily. The medical profession is today in many respects where it was twenty years ago. While science has progressed, the economic aspects of the practice of medicine have remained practically stationary, and it is only within the last few years that the social and economic aspects of medical service have begun to impress themselves upon the profession in general.

With the conservatism for which it is noted the profession has combined an ignorance of non-medical affairs which is inexcusable, the result being that they now find themselves face to face with a condition which is easily comparable with the State control of all medical service as foreseen by the English dramatist and which is called "sickness insurance," or better, "health insurance."

In Germany more than thirty years ago the insurance of the industrial worker began with workman's compensation insurance for industrial accidents and the limits of this insurance have gradually increased until the benefits are now open to almost every wage earner in the entire country for every case of accident or ill health occuring during the period of employment. It includes not only the wage worker but his family and dependents as well.

In England the Insurance Act has been in force since January, 1913, nearly 15,000,000 persons being included under its provisions. Upon its introduction the British Medical Association accepted the terms of the act and in July, 1913, it was estimated that nearly 20,000 physicians (about 90 per cent) were employed by the State in the administration of the law. It has been estimated that over $20,000,000 was paid in fees to physicians on the panels, the average amount being a little over $1000 to each physician.

If a similar law is to be enacted in New York State, and such a law has already been introduced in the State Legislature, it is evident that before the medical profession undertakes the State service it would be wise to examine into the relations between the physician and wage earner under the English act, thereby attempting to settle upon the plan adapted to the best interests of those parties most concerned, namely, the physician, the insured employee and the State.

With the introduction of the act in England physicians who were willing to treat patients under the act were placed upon a panel and patients were allowed to choose their own physician, the proviso being made, however, that the choice must be made for a period of not less than one year. Physicians are paid a per capita fee of seven shillings a year, this being understood to include ordinary medical care but not to include surgery or any special treatments. No limit is placed upon the number of patients on a given physician's panel, nor is any limit placed upon the amount of attention which the insured may demand.

Recent records are unreliable for purposes of forming an opinion as to the working of the law, principally because of the war which has dislocated industries and thrown the medical profession in confusion since August, 1914. At that time the act had been in force nineteen months and numerous articles had appeared in the *British Medical Journal* in praise and criticism of the law. At that time the discussion centered almost entirely upon the determination of the best system for the care of the insured.

The panel system had been found wanting and something more was required to accomplish the desired ends. Immediately two opposing camps sprang up; those who believed in the retention of the panel system—with improvements and additions it is true—but in the main, the old panel system; and those who believed that the best ends would be served by the inauguration of a State health service along the lines of medical service in the army or navy.

Sir John Collie,[1] a strong advocate of a system of State medical service, says in part: "Under the panel system many physicians are overworked. One physician stated that during one week he treated 320 people for colds. This was less surprising when it was shown that this same man with his five partners had 7000 workmen on their panel. Dr. Cox stated that during the year 65 to 70 per cent of those on the panel make some call upon their physicians. A Dr. Salter stated he saw on an average of 168 patients a day. Allowing nine hours a day, this worked out 3¼ minutes per patient of which 1¼ minutes were taken up in clerical work. The patients were obliged to wait an average period of over two hours."

It is apparent that a system such as the above is far from ideal. It was believed, before the

1. Collie, Sir John: A State Medical Service vs. A Panel System. *British Medical Journal*, August 8, 1914.

panel system went into effect, that because the panel included almost all of the practising physicians, the workmen would be more or less evenly divided among the panel members. This, however, has not proven true. Physicians began to be divided into two classes, those who, so to speak, specialized in panel cases, and those who were willing to undertake little or none of the insurance practice. The inconveniences to the physician were many. The clerical work was considered excessive, the work was exacting, and vacations were difficult to secure. When treatment is contracted for during the entire year for less than two dollars per capita it becomes a hardship to devote the required time to this type of practice unless the number of patients under the physician's care is sufficient to guarantee a yearly income of at least fifteen hundred or two thousand dollars. That is to say, it may be very difficult to secure treatment for fifty or a hundred patients, even when they can be easily handled in addition to a physician's regular private practice, while it is comparatively easy to secure a man who will devote his entire time to the care of this type of practice when the quarterly check amounts to five or six hundred dollars.[2]

An additional disadvantage of the panel system is seen in the giving out of disability certificates. Physicians become very lax in this respect and a certain type of workmen flocks to the man who has the reputation of giving many disability certificates. To quote further from Sir John Collie: "It has been said by one who is a strong advocate of the panel system that it is good because 'medical men compete with one another for increasing remuneration by pleasing the patient which makes the administration of the act so difficult.'" Once inaugurated in America, the panel system will find as many adherents as it has found in England, and it will have as many, if not more objectional features.

It may be, and indeed has been, urged that a State medical service is socialistic in character. This may be true, but, if it is, then the system of State insurance is socialistic, and so are many of our modern institutions. We have to do to-day, not with scholastic discussions of what constitutes a socialistic medical service, but rather what type of service is best adapted to the so-called socialistic institutions of the present. State health insurance is surely destined to a trial in the United States before many years have passed, and when it does come it would be well to find the medical profession prepared.

The profession is handicapped by division in its ranks and by lack of organization in dealing with economic problems. The point has not yet been reached where a State medical service for the entire population is either wise or advisable; but the nationalization of the medical services to the industrial army is urgently called for. Such service should include, in order to make an arbitrary boundary, all wage workers earning less than one hundred dollars monthly. Whether the medical service should be whole-time service exclusively, or whether it should include part-time workers in addition to the whole-time staff, can be decided later.[3] "There is, however, one sine qua non in such a service," writes Sir John Collie, "and that is the medical officer must be well paid, have a good position, and the number of patients allotted to him must not be excessive. I have yet to learn that salaried whole-time medical officers of health are not enthusiastic, progressive and capable and that the fact of their not being paid by fee has militated against their attaining their deservedly high position. The salaries for whole-time services would be graduated and there would be as in the army and navy, positions of increasing responsibility and remuneration." He further outlines the State service as having facilities for laboratory examinations, X-rays, etc. Consultants and hospitals would be easily available. The service would entail regular hours and regular holidays, more time for the enjoyment of the home, more time for postgraduate study, and a permanent freedom from anxiety caused by fluctuations of income; in fact, entire freedom from the commercialism of the present system.

Even were these facts given under a lesser authority than the above they would be striking enough to demand consideration, but they are emphasized because of their potency rather than because of their origin. They represent the trend of thought in a country where state insurance under the panel system has had a trial of more than a year, and the result is unsatisfactory to all parties concerned. The patients are dissatisfied because the service is inadequate; the physicians are dissatisfied because the pay is small and the clerical work is arduous; and finally, the State is dissatisfied because the expenses are high (especially for drugs) and because of the belief that the periods of disability are unduly prolonged. To the outside observer it is apparent that science is not being advanced to the same extent it is in the army medical service or as it is in the very excellent medical services of the Board of Health in most of the larger American cities.

If changes in medical customs and practices are wise and advisable, it is desirable that the suggestions for such changes come from, rather than be forced upon, the medical profession.

In an address before the Associated Physicians of Long Island, Rubinow states the whole situation clearly and concisely, saying in reference to social insurance, "In this the medical profession is hopelessly behind the times. In its worst phase private medical practice is medically from twenty-five to fifty years behind the present status of medical practice and surgical skill. In its best phase it is a luxury which, like automobiles and private yachts, can be purchased only by the selected few. The socialization of medical service has been woefully delayed as compared with other functions of lesser importance, but at last it is on its way. The purpose it must accomplish is twofold—improvement in quality and cheapening of cost. These purposes cannot be easily accomplished in the face of obstinate opposition from the medical profession."

It were wise if the profession as a whole were more interested in the subject of medical economics. Are we really as scientific as we claim to be if we allow many of our efforts to go to waste because of lack of organization? Concerted action and co-operation will do more to advance medical science and the wellfare of man than will even the best type of individual effort. Consequently it is advisable that organizations composed of medical men throughout the United States combine to lay

[2] Sir John Collie mentions one physician who had 2,800 patients on his panel and who worked from 9 A.M. to 11.30 P.M. 365 days in the year.

[3] The writer has published elsewhere a plan for a State medical service which he believes to be open to few objections.

before the law makers what we, the profession, consider the ideal provisions for the medical administration of an industrial health insurance law.

110 West Seventy-ninth Street.

SPEECH, ITS CULTURE AND REFINEMENT; WHAT IS DONE FOR IT IN HOLLAND.

By N. J. Poock van Baggen,

The Hague, Holland.

My readers, did you ever meet with that certain handsome young lady, dressed by a first-rate Paris dressmaker, smart and "Ciln soignée" from top to toe, who moves about so gracefully and looks so extremely distinguished and refined? Fascinated by so many charms you are only too happy to obtain an introduction and to be allowed to speak to her. When she opened her lips to respond to your modest flattery, I noticed a sort of bewildered look in your eyes, which bye and bye changed into an ironical smile. What was the matter—this outwardly distinguished and refined young person betrayed only too distinctly her low origin both by her voice and accent.

Poor young lady! She had spent so much for her general refinement and culture, and only forgot an essential matter: the culture and refinement of her speech.

Sometimes you go to church, I suppose. Going home you want to think over the beautiful words which the clergyman uttered, but it is too much for you. You got a bad headache while listening to the sermon. You overstrained yourself in the effort to understand the speaker, and you came to the conclusion that the sermon failed to make the desired impression because of the fatiguing resonance of the clergyman's voice and his want of distinct articulation.

And the clergyman himself . . . He did his utmost effort to make himself understood in the spacious church; but before he had finished half of his sermon, he had the desperate feeling that his voice was losing its clearness and became hoarse and indistinct. He came home with a sore throat and the unpleasant feeling that his audience had not come under the spell of his eloquence. Yet he had carefully meditated his subject and his sermon was well prepared. He only never thought of training and preparing his voice for its strenuous task. And this is the same case with ever so many speakers. How often does it not occur that, in the midst of an electioneering campaign, the candidate is forced to renounce speaking at a meeting because his voice has given out entirely. And no wonder! What fighter, gymnast, pianist, violinist or any other performer will go in for a performance without having thoroughly prepared and trained his muscles by appropriate and efficient exercise? They know too well that their success depends on the readiness of their muscles for the task. While in the United States, I noticed that the public speaker, as a rule, never thinks of getting his voice ready for the work.

The American speaker does not seem to realize that the voice and speech is the result of the action of a complicated and delicate set of muscles, which need more than any of our muscles to be properly trained when we demand a great exertion of them. Yet the speaker who masters the right employment of the voice will meet with the pleasant experience that his voice lasts till the end of his task. Serenely, in full possession of his faculties, he faces his audience, who follows with pleasure his intelligible and comprehensible speech.

It is a matter of course that the training of the voice includes its refinement. Vicious accents, as for instance the nasal twang, disappear altogether or are diminished sensibly when the muscles become more supple and tractable by their exercise.

How do we train the voice? I mean the fundamental training, which has in view the exercising and strengthening of the muscles used when speaking and singing and the furthering of the harmonious co-operation of the different groups of muscles.

When we observe a speaker or singer, we notice that, before he begins to produce a sound, he inhales more or less deeply. This inhalation procures him the provision of air which he uses as the motor power to put his instrument into action. We can compare this inhalation with the work which the bellows blower does for the organist. Without the necessary provision of air the organist is unable to play his instrument. Only after the bellows are put in action and he has the management over a sufficient quantity of air or, what is here the same, a sufficient quantity of motor power he can draw sounds from his instrument.

Exhaling, the speaker or singer uses this provison of air to make the tented vocal cords vibrate. This vibration engenders the sound, which we call "the voice." From the voice box the voice or sounding breath is driven into the pharynx, the mouth, and the nose. Those parts assume by means of the articulating muscles the different attitudes and shapes necessary for the formation of vowels and consonants, which as such leave the mouth and reach our ear.

The sonorous vibrations of the voice cause the co-vibrations or resonance from the partitions of the vocal instrument, i.e., of the thorax, the larynx, the pharynx, the mouth, and the nose with its cavities. This co-vibration or resonance gives the tone, its characteristic quality or "timbre," its brilliancy, and its fullness.

From the above results we learn to distinguish in the speaker and singer four elements: (1) A motor element (the breath); (2) a vibrating element (the voice); (3) a forming element (the articulation); (4) a resonant element (the co-vibration of the walls of the vocal instrument).

Thus for the training of the speaker and singer we consider in the first place the breathing. If the breathing is faulty and weak, it is corrected and strengthened by appropriate exercises, after which the pupil is taught how he can best use his breath on behalf of his voice and articulation.

Secondly, the articulating muscles are examined and the different vowels and consonants reformed so far as necessary. Nearly at the same time the amelioration of the action of the vocal muscles is undertaken; while finally the resonant element is developed.

Normal speech and singing depend on the faultless action and the exact harmonious co-operation of the four elements. This co-operation is so strict that even the least deviation of one of the parts is of direct influence on the other elements.

A faulty articulation, for instance, impedes the action of the vibrating element and requires a greater effort on the part of the breathing muscles; while, on the other hand, a wrong use of the breath thwarts the distinct pronunciation of the vowels and consonants as well as the voice production. And also a non-developed resonance or

gaps in this element are an important impediment to the clearness and purity of the voice.

Very many times I have been asked in America if, when I speak of the training of the voice, it is elocution that I mean.

It is not. The training of the voice precedes the lessons of the elocutionist. This training is given by what we call here the "leeraar in het methodisch spreken," which means: "Specialist or expert in normal speech and voice hygienics."

The sphere of action of the expert implies not only the training of the healthy voice but also the treatment of all the voice afflictions which appear after serious diseases of the throat such as diphtheria, angina, etc., and after those affections caused by the too general misuse of the voice as well as by speakers as by singers. Most of the time the expert is also specialist for correcting speech impediments and for gymnastics of the respiratory organs.

The expert works in combination with the medical specialist in diseases of the throat and respiratory organs. No serious expert begins his work before the patient has gone through a judicious medical examination.

The studies of the student-specialist for voice hygienics include the exact anatomical knowledge of the vocal instrument, the pathology of the throat and of the voice, the diagnosis, the modes of treatment, and the application of the exercises in the different cases, tone production, acoustics, and phonetics. If he goes in for the breathing and the speech impediments, he studies also the diseases of the respiratory organs and the central and peripheral speech affections, their origin and treatment.

With regard to the treatment of the voice, affected through misuse or illness, I can say that I have found it nowhere so complete as in Holland. During my investigations regarding the care for the voice and the culture of speech in the different countries, I have been astonished to find that in some countries this special treatment is altogether unknown, as for instance in France and in the United States; while in other places, as in Berlin, it was introduced by Dutch specialists and received with general appreciation.

Since the last twenty years the culture and refinement of speech in Holland has largely improved. The conservatories for singing at Amsterdam and at the Hague, as well as the school for actors and actresses have long had their own expert specialist and every pupil is obliged to go through a severe treatment for general voice hygienics and purification of the accent.

Particular care is also given to the training of the voice and the refinement of the speech of the teachers. To every Dutch training school for teachers is attached nowadays a specialist for voice hygienics who is salaried by the government or by the municipality to which the school belongs. Moreover, in the large towns, as in the Hague and Amsterdam, the municipality has appointed a specialist for voice hygienics, who gives courses free of charge to the teachers of the municipal schools. Those courses were started to combat the throat disease (the same as clergymen's sore throat) to which the teachers, in the exercise of their profession, are so frequently subject.

When the teachers suffer from the throat the visiting physician of the school examines them and, if necessary, sends them to the courses for voice hygienics. For the teachers with a healthy voice those courses are not obligatory but on his (or her) demand, he (or she) can follow the course. Generally all the teachers of the municipal schools take a course because it gives them a better chance for an appointment and for promotion when they have a well-trained voice and refined speech.

It is a matter of course that those trained teachers exert a favorable refining influence over the speech of their pupils. I have often noticed that the young teachers, who have followed the course take pleasure in correcting the speech and purifying the accent of the children, who are under their care and demand from them a faultless pronunciation.

Besides the care for the voice and for the refinement of the speech in general, the speech defects are specially attended to.

In every town of some importance there is nowadays a specialist for speech impediments, attached to the public schools and salaried by the municipality. In the large towns, as Amsterdam and the Hague, the specialist has a staff of assistants. They visit the public schools regularly and at the request of the teacher examine the pupils who suffer from any speech defect. After the diagnosis is made the children go to the municipal institution, where they receive free of charge the treatment which their case demands.

Some years ago the specialists for voice hygienics in Holland founded the Dutch association for the speech culture, which meets regularly. In those meetings special cases are discussed, and in particular the measures to be taken to further the general culture and refinement of speech are advocated.

The influence of the refinement of speech is not merely external. I have explained above how speech is produced by the action of some groups of muscles. Those muscles are stirred by the vibration of the nerves. They vibrate under the impulse of the action of the brain, which is the utterance of the soul. Thus speech comes from the soul to go to the soul.

And so the culture and refinement of speech mean the smoothing down of the obstacles which hinder the free communication of the souls.

The culture and refinement of speech mean the furthering of the better understanding between mankind; and that better understanding between mankind is what we require nowadays, essentially; there is no doubt about that.

Plaats 16.

MEDICAL EDUCATION IN CHEMISTRY.

By FREDERICK S. HAMMETT, PH.D.,

Los Angeles, Cal.

College of Physicians and Surgeons, Medical Department, University of Southern California.

That the average physician possesses but little if any applicable knowledge of chemistry is lamentably self-evident. To one trained in chemistry, and especially trained in the applicability of chemistry to medicine, this general lack of information on a subject so vital to efficient understanding of the reactions of the body is prominently apparent.

This elemental deficiency in education is shown by the absence of reported productive discussion, in either council or publication of the needs of the physician for a well-grounded knowledge in the application of the principles of chemistry to medicine.

Personal conversation with several physicians of more or less successful practice has invariably brought the information that they "never knew chemistry and never could understand it anyhow."

This lack is also obvious when one glances over the examination questions asked in chemistry by various State Boards. To what practical use can a physician put the formula for common salt? Why should he know a test for ferrous salts? Of what value to him is the knowledge of the names and structures of three hydrocarbons? This is high-school chemistry and belittles the value of the science in the eyes of the young graduate instead of showing him that there is a definite correlated knowledge of chemistry which he is expected to know as capable of direct application by his profession.

Then turn to the requirements of the Association of American Medical Colleges as set forth in their Constitution and By-Laws. Here again lack of scientific viewpoint obstructs the vision and confuses the desired end, due in its entirety to improper conception of the science and hence inability to so plan a curriculum as to bring out the coördination necessary for just appreciation. The unnecessary and pedagogical redundancy requiring 192 hours of premedical training in college grade chemistry (not to mention that required in high-schools), presumably inorganic and organic, and then requiring 180 hours of inorganic and 75 hours of organic chemistry during the medical course is so obviously an example of the lack of perception of values as to require no further comment. And then to top it off only seventy-five hours are given over to instructing medical students in the applications of chemistry to medicine, that is, physiological chemistry.

This, however, does not constitute or imply a lack of appreciation of the value of the science of chemistry to medicine. In fact the mere inclusions of the subject in both premedical and medical courses show that it is a valued adjunct to the profession. The very requirements of the Association of American Medical Colleges show this appreciation, not only by the generous time alloted to the subject, but also by the equipment demanded and the fact that research is encouraged and expected.

The constant occurrence of articles in the scientific journals founded on chemical studies of both normal and pathological organisms; the establishment of laboratories in hospitals for the chemical study of the cases at hand and the routine analytical procedure as follow-up of the treatment; the employment in these hospitals of chemists trained in medical research; the trend of medical schools toward preferring men trained in the science and especially in the practical applications of the science to medicine, to instruct their students, rather than employing as teachers practitioners whose only excuse for teaching lies in the desire to be connected with a medical school and thus enlarge at one and the same time their prestige and their practice; the establishment by medical schools of laboratories for research along chemical lines and the requirements that the instructors be capable of contributing something to the advancement of medicine; the many institutions devoted to medical research alone; the eagerness with which the average physician grasps these discoveries and applies them to his experiences, especially at present evident in the use of the glands of internal secretion; all of these and many more bear fruitful evidence that in spite of the general lack of definite information there is specific appreciation of the value of chemistry to medicine.

Now, what are the causes of the general lack of knowledge of the practicability of chemistry as applied to medicine?

In the first place the study of biochemistry or the chemistry of the living organism is comparatively recent. That is, the accumulation of evidence of a chemical nature relating to the processes of life has not been sufficient, until within the last few years, to warrant the application of the principles evolved. Consequently the training of medical students has been along the lines of straight chemistry with but little, if any, practical application, and the subject was looked upon, and justly so, as a waste of time. It is only within recent years, and even then at only a few of the more advanced medical schools, that advantage has been taken of the progress in chemistry in its use for medicine and the subject given its full value. Hence we have the majority of physicians possessing a false conception of the science and exerting their influence upon the minds of the present-day medical student to make difficult the instillation of its practicability.

Moreover, the insufficiency of the premedical training along the lines of definiteness, adds to the difficulties of imparting understandable information. This is encouraged by the lack of scientific attitude and understanding in the profession generally.

Chemistry as largely taught either is in the hands of some practitioner whose chemical training has been received from other similarly situated individual, or else is in the hands of a chemist whose training has omitted the medical viewpoint. The former lacks chemical understanding; the latter, medical understanding. From the first man the student gets neither chemistry nor its application. From the second man the student gets chemistry but no practical usage.

Another cause for the present day inadequacy of chemical knowledge is the type of questions asked by State Boards. By the very fact of their impracticableness they cast their shadow upon the subject and thus oppose a barrier to progress by removing incentive. As the chairman of one State Board said to me recently, "Chemistry is the last subject to be given out, and it is always shoved off on someone because no one wants it." And I say no one wants it because the average physician has no understanding of its applicability to his profession.

Furthermore, there is a certain group of physicians who, having specialized in one branch of medicine, have had no opportunity to keep up with the progress made in other lines, and because of their lack of preparation and improper instruction fail to see the importance of chemistry. These men, otherwise broad-minded, by derogatory statements exert an inhibitory influence upon the minds of the younger and less experienced men, who, revering the older and wiser heads, imbibe their point of view and bring to the subject a wholesome contempt that is the part of youthful prejudice.

The sum total of lack of preparation, impractical instruction, impractical State Board examinations, and unappreciative critics has tended, and at the present time tends, to bring disrepute upon a subject that, if properly understood, is an invaluable practical asset to the physician.

A little intensive thought will make clear why a greater appreciation is due the subject, why a better understanding is necessary, and how much the medi-

cine of to-day is dependent upon the fundamental principles of chemistry.

Anatomy teaches how the body is put together. Physiology teaches how it works; but Biochemistry teaches why it works. The *how* is only controlled by an understanding of the *why*.

The body, composed as it is of an indefinite number of units called cells, is a vast chemical factory each unit of which has a purpose of its own and the successful carrying on of whose function is governed by the laws of chemical reaction. It is thus obvious that a knowledge of the *why* of bodily activities is ultimately grounded upon a knowledge of the principles of chemistry. And as both structure and mechanism are but supplementary to motive power, so a knowledge of chemistry is a prime essential to the understanding of the living organism.

The maintenance of life depends upon an adequate supply of energy-producing material to the body and the removal of the products of its combustion. Hence a correlated knowledge of the chemical nature of what goes in, what changes it undergoes during its passage through, and in what forms it is excreted is essential to the understanding of bodily processes. Without this information the physician lacks just as much and even more of being adequately prepared to deal with the human body as if he knew nothing of anatomy or any other kindred subject.

If this were all it would be sufficient to command not only a deep respect and appreciation of the value of chemistry to medicine, but to also show the necessity for a greater understanding. But this is not all.

The work of Dakin on body oxidations, of Knoop on fat decomposition, of Moore and Rockwood on fat absorption, of Jones on nucleic acids, and of Folin on protein metabolism are but a few of the innumerable examples that could be cited wherein Biochemistry has opened up new views for medicine and afforded a working basis for future treatment that can be equaled by no other science.

The development of microchemical methods for the analysis of urine, blood, and feces has put into the hands of the physician rapid, easy, and accurate means for studying body processes and following through pathological progress to its completion. Combining the use of these methods with an understanding of the causes giving rise to the results obtained affords the clinician invaluable diagnostic measures. It is accordingly obvious that those schools whose aim it is so to train their students that on entering the practice of medicine they shall be equipped to take their place in the front ranks of their profession, must take cognizance of the value of biochemistry and so incorporate it into their course of study that it becomes second to none in importance.

Admitting then that the average physician does not understand the practicability of chemistry for his profession; that present methods of curriculum planning fail to allow opportunity for the development of this understanding in the medical student; that the present type of State Board questions in chemistry fail to demand a careful knowledge; and that in view of the usefulness of the science to medicine radical reformation is needed, the following suggestions are offered for consideration:

The premedical requirements should be definitely outlined. The progressive medical schools of this country are requiring of their students a two-year college course as a premedical requisite. Without undue elimination or too strenuous endeavor on the part of the student the following courses could well be required before granting admittance to medical schools: One year in general inorganic and physical chemistry, one year in organic chemistry, and one half-year in quantitative analysis. With a foundation of this sort any intelligent medical student is ready to commence the study of biochemistry and is capable of understanding its applications. The requirements of the Association of American Medical Colleges as regards chemistry in medical schools should be changed.

With a foundation as outlined above, or even with the present requirements of the Association, it is not only unnecessary but even a waste of time to include in the medical curriculum inorganic and organic chemistry. It is a waste of time, because in the first place the student is supposed to have had these subjects before entering upon the study of medicine, and in the second place because the purpose of the medical school is the study of the human body. Nay, more, it is a wicked waste of time. For here we are clamoring for a fifth year of medical training and claiming that four years is too short, and then valuable time is filled up with repetition. Change this, eliminate the elementary branches in chemistry from the medical curriculum and apply the time thus released to the study of biochemistry.

This is not a plea for more time for chemistry in the medical schools, but is a plea for more time for its practical application and the elimination of subjects properly supposed to be taught in the premedical course.

Concomitantly with these changes there must come a recognition of the responsibilities of the State Board Examiners as regards chemistry. They must realize that what a student knows is what he thinks he is going to be asked on examination, and not what his instructor has tried to teach him. From the standpoint of the teacher this is pernicious; but how eradicate it? We cannot teach all men the value of high ideals. We can tell the student that the deeper his knowledge goes the better service it will be to him. But with all the present day struggle of competition, the rush and hustle, and the crowded curriculum, the average medical student has but little inclination to dig deep and find the sweet water of knowledge. Rather he is so thirsty, so hurried, that he drinks from the braken surface pool of information, content in having assuaged his thirst for the moment, not considering that the more wholesome water of learning lies deeper, only awaiting his efforts to obtain it.

It is not a difficult thing to set a high standard of questioning that will be reasonable and at the same time demonstrate the practicability of the subject. For instance, why not find out if the young doctor knows the sources of the acetone bodies in the blood and urine, or why gelatine is an imperfect food, or what becomes of the nitrogen we eat, how and in what form it is excreted? Even the physical chemistry of indicators as applied to the determination of urinary acidity would not be too intricate. Nor to know something of the mechanism for the maintenance of the neutrality of the blood. Should he not know that cane sugar is not utilizable as a food when injected intravenously and why?

Why not be logical? Why not look the proposition squarely in the face, admit the incongruities, and eradicate the present absurd condition? Why continue to hamper the future medical student by a dogmatic clinging to moss-grown ideas?

Let the attitude of the physician be to *cure*, not merely to relieve. And just as the understanding of the *how* and the *why* of the cure rests upon a knowledge of the reactions of the body, and as this knowledge is firmly based upon a knowledge of chemistry, so does the efficient education of the physician depend upon an efficient instruction in the applicability of chemistry to medicine, which can be obtained only by a broad-minded acknowledgment of the present systemic deficiencies and an earnest attempt to bring about the necessary changes.

Medicolegal Notes.

Use of X-Ray in Diagnosis.—In an action for malpractice it appeared that the plaintiff fell off a ladder about 15 feet, injuring his ankle. He was given a hypodermic injection to relieve the pain, taken to a hospital, placed upon an operating table, and the defendant and another doctor made an extended examination of his ankle, spending over half an hour in doing so. They diagnosed the injury as being a severe sprain. The ankle was placed in splints and the patient placed in charge of a nurse, who was instructed to pour liniment upon it. The case was then given over to the defendant. Three or four days after the injury the splints were removed, the foot placed on a pillow with a sandbag to support it, and the nurse was directed to massage the ankle and move it as much as the patient could stand. This was done each day. He remained under the defendant's care in the hospital 17 days. At the time he left he was unable to bear his weight upon the injured foot without pain or to walk without crutches, and finally the foot remained fixed in such a position that the front part of the foot was left at a downward angle from the normal position. Two months after the injury he suggested to the defendant he would like an *x*-ray taken. This was done by another doctor. It disclosed that the fall had caused a slight impacted fracture of the forward part of the astragalus and a rupture or raising of the periosteum on the posterior portion of this bone. A fluid exuded which afterwards hardened into a bony substance and formed a wedge between the articulation of the tibia and astragalus, thus causing the abnormal position of the foot. Four physicians were called by the plaintiff. One of them, who took the *x*-ray pictures, testified that an *x*-ray picture taken at or about the time of the injury would not have disclosed the condition with reference to the periosteum or the effusion of the fluid; that the proper treatment for the impacted fracture would have been to keep the foot at rest by means of splints for six or eight weeks. He also testified that if, when the defendant examined the plaintiff's ankle and found swelling, mobility, no displacement, no dislocation, and no crepitation, his diagnosis in the first instance that his injury was a severe sprain would have been the diagnosis of an ordinary practitioner of the allopathic school of medicine in Omaha about that time, May, 1912. The other three witnesses called by the plaintiff testified substantially to the same effect, though one or two said that if the patient would stand the expense he would, in case of doubt, or under such circumstances, have had an *x*-ray picture taken. None, however, testified that this was the usual method. It was held that the testimony did not establish that the failure to have an *x*-ray picture taken as an aid to diagnosis constituted lack of reasonable care and skill under all the surrounding circumstances, and that if the plaintiff's case rested upon the claim of negligent diagnosis alone the evidence would not support a verdict in his favor.—Van Boskirk v. Pinto, Nebraska Supreme Court, 155 N. W. 889.

Prescriptions of Unusual Amounts of Narcotics.—The federal district court, N. D. New York, holds that under the exception in Section 2 of the Harrison Narcotic Law of prescriptions by physicians, a physician who issues a prescription for an unusually large amount of the drugs, which prescription shows on its face that the quantity prescribed is unreasonable and unusual, or a dealer who fills such a prescription or order issued by a physician, is guilty of an offense, unless the prescription indicates the necessity for such an unusual quantity.—United States v. Curtis, 229 Fed. 288.

Construction of Harrison Narcotic Act—Sending Medicine Through Mails.—The federal district court, S. D. Ohio, holds that, while the Harrison Narcotic Act of December 17, 1914, permits a physician in the course of his professional practice to dispense and distribute the mentioned narcotics to a patient by whom he is employed to prescribe, without being subject to the prescribed regulations, although he does not personally attend the patient, the act must be construed with reference to the known usages and modes of practice in the profession in which the prescribing for patients without personal examination is the rare exception and not the rule; and under the provisions of Section 1, requiring the Commissioner of Internal Revenue, with the approval of the Secretary of the Treasury, to make all needful rules and regulations for carrying the provisions of this act into effect, the commissioner has authority to prescribe what shall constitute "personal attendance" and "professional practice" by a physician within the meaning of the act, and a regulation which denies the right of registration and exemption to one who, although a licensed physician, does not see most of his patients, who bases most of his prescriptions on their written statements sent to him through the mails, and who prescribes the same remedy for all alike, is within the power conferred and valid.—Tucker v. Williamson, 229 Fed. 201.

"Chiropractics" Is "Practising Medicine" in Utah.—Utah Laws 1911, c. 93, provides that any person shall be regarded as practising medicine who shall diagnose, treat, operate upon, prescribe, or advise for any physical or mental ailment or any abnormal mental or physical condition of another after having received or with intent to receive any compensation, or who holds himself out as a physician or a surgeon. The Utah Supreme Court holds that a "chiropractor," one professing a system of manipulations which aims to cure disease by the mechanical restoration of displaced or subluxated bones, especially the vertebræ, to their normal relation, who advertised as a "Graduate chiropractor—no drugs or surgery, or osteopathy—try chiropractic," and who endeavored not so much to cure ailments as to permit the natural "vital forces of the body," impeded by luxation of vertebræ, to proceed unhindered to any diseased part upon readjusting the displaced vertebræ with his bare hands, for which he received compensation, was "practising medicine" within the statute, since he "diagnosed" the symptoms of his patients by recognizing the presence of disease from its signs or symptoms in deciding as to its character, and thereafter treated them for compensation. "There are," the court said, "many ailments in their acute stages which, if correctly diagnosed and properly treated, yield most readily, but if not recognized and not properly treated become in their chronic stages most stubborn and unyielding. The defendant undertook to treat various ailments of children without even professing any knowledge of pediatrics, and many other ailments where knowledge of histology, biology, pathology, and other branches of science was essential to properly recognize and understand them. It needs no argument to show the harm that may result by anyone without knowledge of opththalmology attempting to treat some acute and virulent disease of the eye by attributing the cause of the disease to a subluxal vertebra of the neck causing "nerve pressure, or that the manipulation to reduce the pretended subluxation might itself do harm, but that in the meantime the disease, for want of recognition and proper attention, may have progressed to a stage where it no longer can be arrested."—Board of Medical Examiners of the State of Utah vs. Freenor, 154 Pac. 941.

Testing Cocaine.—In proceedings against a physician for unlawfully selling cocaine, the physician testified that he gave a person (who appeared to have been given to the use of cocaine and liquor) a powder composed chiefly of chloretone, and which contained no cocaine. This person's evidence as to whether he asked for cocaine was contradictory. Two physicians, both admittedly unfriendly to the defendant, testified that they tested the powder by tasting the contents only, and upon such test pronounced that it contained cocaine. Upon cross-examination each of these witnesses was shown a medical work and his attention called to the following statement: "Cocaine responds to all the general tests for alkaloids, giving precipitate for tannic acid, picric acid, solutions of iodine, etc., but these are not distinctive, nor, unfortunately, do we possess at the present time any one characteristic test for this alkaloid." Neither of the witnesses disputed the correctness of this statement. It was held that on such evidence a conviction could not be sustained.—Stadler vs. People Colorado Supreme Court, 147 Pac. 658.

SPLENECTOMY IN PERNICIOUS ANEMIA.

THE occurrence of enlargement of the spleen in certain anemic conditions, such as hemolytic jaundice and Banti's disease, and the absence of any rational method of treatment led inevitably to the therapeutic removal of the spleen in some of these cases. The spleen has long been considered as the center for normal red cell destruction, and in some instances of splenectomy for rupture of the organ in otherwise normal individuals there followed the development of a polycythemia. A very definite improvement was seen in many cases of anemia associated with splenomegaly after the spleen had been removed and naturally that measure began to be adopted in the treatment of other more or less closely allied conditions. It was tried in a number of cases of pernicious anemia and the results were at first remarkable. The operation is a serious one and many of the patients in grave condition so that the mortality was rather high. But when the patient survived there followed a marked stimulation of the whole bone marrow and a remission in the course of the disease. With the appearance of the reports the operation became immensely popular and large numbers of spleens were removed, often, it is feared, without sufficient justification. Then reports began to tell of later deaths and recurrences and the method was decried as dangerous and of only temporary value. As usual the truth is somewhere between the two extremes.

The subject has been reviewed in two recent articles by Lee, Minot and Vincent and by Krumbhaar (*Jour. Amer. Med. Assn.*, 1916, Vol. LXVII, pp. 719-723). A critical study of the reported cases has shown the authors that the immediate mortality of the operation is probably much less than the apparent 20 per cent. if the cases are properly selected. A red cell count of less than 1,000,000 is apparently a rather strong argument against operation. A true estimation of the effect of splenectomy in pernicious anemia is somewhat difficult because the disease is characterized by the occurrence of remissions which may come on at any time and be marked and lasting. It is because of this fact that so many therapeutic measures have had such brief vogue in this condition. Still it is shown that a remission practically always follows the operation and that splenectomy is probably the greatest bone-marrow stimulant at our command.

So far there is little difference of opinion. It is in the later study of these cases that the important information is to be obtained. In about one-third the improvement extended over a period of two years although there was no evidence that there occurred any real cures. Better results were seen in those patients in whom the spleen was definitely enlarged and Krumbhaar points out the possibility that in the future it may be shown there are two or more distinct diseases which are now called by the one name and that splenectomy is indicated in one but not in the others. It is pointed out that transfusion also results in stimulation of the bone marrow and that it is a measure not serious in itself and which can be frequently repeated. For that reason it is generally preferred to the operation. Our lack of definite knowledge concerning many of the important factors in the problem prevents our arrival at any conclusions of much force.

At the present time it seems to be the opinion of the majority that splenectomy is more apt to have a favorable result in those cases with clinically enlarged spleens, icteroid appearance, and increased urobilin output (increased hemolysis) without increased resistance of the erythrocytes. While it is properly considered as an operation to be undertaken only as a last resort still the results are better in those patients in whom the disease has progressed for not more than a year and who still have a relatively good blood picture. The operation should be preceded by one or more transfusions and may be followed by them if necessary. It is probable that the next five years will see fewer splenectomies done for pernicious anemia than did the last three years, but the results will be much more favorable and it is possible that with increased knowledge it may become feasible so to select cases that a favorable result can be predicted with some surety.

ACUTE ANTERIOR POLIOMYELITIS IN SWITZERLAND.

THIS scourge is now existing in mildly epidemic form in portions of Switzerland. During the two years, 1914-15, 130 cases occurred. As 40 cases occurred in the Canton St. Gall, 36 of which were in 1915, the affection may be regarded as epidemic for that locality. The same may be said of the Cantons of Lucerne and Zurich, although the number attacked there was much smaller. The total of victims of the three Cantons was but 75. The fact that many of the cases appeared in the autumn of 1915 did more to justify the notion of epidemicity than the number of cases.

In the *Correspondenz-Blatt für Schweizer Aertze* for July 29 Androussieur gives his experience with the Lucerne cases. The smallness of the material in the community made it easy to trace the apparent contagion. Thus one boy of 6 was believed to have given the disease to a playmate aged 4, and the latter to have infected a brother aged 13. The incubation period was apparently two and three days respectively. The first victim contracted his disease from a source wholly unknown. The symptoms were much the same in all—headache, stiff neck, vomiting, marked sweating, pains in the limbs,

fever, etc. The disease ran a relatively mild course and the prospects of functional recovery seemed to be good. One patient made a complete recovery in two or three days. In a second group of ten cases a woman of 32 came down suddenly with high fever, headache, stiff neck, and profuse sweating. The symptoms went from bad to worse, death occurring on the sixth day with respiratory paralysis. A man aged 41 met the same death in four days. He came down suddenly with fearful abdominal pains, chills, and fever. He complained also of headache and weariness. Later he suffered from unbearable pains in the back. In a boy of 10 one of the first symptoms was follicular angina. In a youth of 16 the only symptoms at first were malaise, chills, and fever. The other phenomena developed very slowly. Another youth of the same age fell ill very suddenly with high fever, but at no time showed any cerebral symptoms, and several other children had the same type of disease.

Certain cases, not necessarily fatal or severe, showed rectal and vesical troubles during the disease. The fatalities were in cases which would ordinarily be termed Landry's paralysis. The two deaths made the mortality of the second group 20 per cent. In this group contagion could apparently be traced in half of the cases, either direct or through healthy carriers. The other five exhibited no epidemiological features. Through these cases it was possible to place the ordinary limits of incubation at from 2 to 7 days, but in two exceptions the length of this period was extended to 13 days and 5 weeks respectively. The epidemic lasted over three months and had its maximum in November.

During the past twenty-five years the author has treated 79 cases in the children's hospital at Zurich, nearly all in children under five years of age. From what we actually know of the virus it behaves much like the virus of rabies. A powerful toxin is produced, as shown by the changes in the nerve cells, *i.e.* it has a striking affinity for the latter. Epidemiologically it seems related to epidemic cerebrospinal meningitis.

ANESTHESIA AS A SPECIALTY.

In certain quarters the impression seems to prevail that any medical student or nurse who knows enough to pour ether out of a container drop by drop and watch a patient's respiration and pulse knows enough to give anesthetics. The presence of the surgeon too seems to be considered sufficient protection, for, ask the supporters of this system, would the surgeon let his patient die from the anesthetic?

The writer gave his first anesthetic in a large hospital in a large city. He had just been graduated from a class A medical school where he had seen about thirty administrations of an anesthetic, that is, he had witnessed about thirty operations at which he had been bidden to watch every move of the operator. He had never even assisted at the giving of an anesthetic, but nothing of this was asked of him. Instead he was given a can of ether and turned loose on a helpless child in an anesthetic room, with no help available but nurses. Fortunately the child lived through it and proficiency came with practice. Several years ago the leading surgeon in a large city—a man with a national reputation—was operating in a hospital where student anesthetists were the rule. The patient, an only son about twelve years old, died on the table from the anesthetic and the hospital and surgeon were sued. As a result a force of three expert anesthetists to serve in rotation were added to that hospital's staff.

No man can attend to two complicated procedures at one time. No surgeon can give his full attention to the operation in progress and at the same time be fully cognizant of the state of the anesthesia. It is not fair to the patient to be operated on by a man whose mind is only partly on his work, neither is it fair to submit anyone to a narcosis, stopping short only of paralysis of the vital faculties, induced by a non-medical person supervised by an occasional glance from a very busy man a few feet away. The technique of anesthetization can be acquired by practice by anyone, doctor, nurse, or student. But when we realize that the first sign of some difficulty with the patient may be so slight as to be observable only by a skilled anesthetist and yet so grave that immediate and appropriate treatment is required if the patient is to live, we at once realize that the knowledge of the expert is indispensable and should be available.

The expert anesthetist should have especial training in the diseases of the chest, he should be well versed in the particular drugs he uses, such as anesthetics, stimulants, and depressants of all kinds. He should, of course, be letter perfect in the mechanical details of his specialty and familiar with all the complications which may arise in the course of an anesthesia. Furthermore he should understand something of psychology and have a pleasing personality which inspires confidence in the patient. Possessing all these qualities such a man need never find himself idle. The surgeon who approaches an operation with a mind at rest about the welfare of his patient under the ether is in condition to do much better work, and the hospital which has the reputation of furnishing such expert anesthetists will before long be the hospital of choice of the well-informed physicians and surgeons in that community.

SALONICA FEVER.

The war has brought out another disease of a somewhat new type, or, at any rate, of a new type to Europeans. Captain I. C. McWalter contributes a paper in the *Medical Press* August 9, 1916, on Salonica fever, presumably a malady indigenous to Salonica and its vicinity or which has appeared and been closely observed only since the allied armies made a base of that Grecian port. McWalter describes it as resembling a cross between malaria and typhoid, aggravated by bronchopneumonia. With the exception of the presence of parasites in the blood corpuscles the affection exhibits none of the characteristics of malaria, no cycle of events, no regular stages, no enormous spleen, no definitely specific effects of quinine. McWalter questions whether every pyrexia where Peyer's patches are inflamed, as is the case in Salonica fever, should be

classed as typhoid. Widal's reaction is sometimes negative, but this may be attributed to antityphoid inoculation. None of the postmortem signs of typhoid fever, malaria, or pneumonia are observed in fatal cases of Salonica fever, that is, to say, no such signs as an observed postmortem at home in cases of these diseases. Most of the cases of Salonica fever, as said above, resemble a complication of typhoid and malaria, with the supervention of bronchopneumonia; others are more like dysentery with malaria and lobar pneumonia, and still others closely simulate sunstroke.

Perhaps the most interesting point mentioned by McWalter in connection with this disease is that it is largely due to diet. It appears to him that much of the severity of the fever is due to the lack of vitamines. Where patients have been living for ten or twelve months in a hot, dusty, insanitary environment on canned food and chlorinated water and they are taken to a hospital where they get a canned food diet, it is difficult for the blood to become charged with that fresh abounding viltality which will enable it to shake off a fever.

The war, and especially the war waged in the East and Far East in which the conditions are peculiarly enervating to the unacclimated European and the food is seldom fresh, has brought out the fact that after all diet is an important factor in the preservation of health. Moreover, many happenings would seem to favor the theory that several diseases are caused by a lack of the vitamine element in food while other diseases are injuriously influenced by this same lack. It has been demonstrated to the satisfaction of most authorities that beriberi is a malady caused by absence or lack of vitamines. In this country a great deal of evidence has been brought to show that pellagra is caused by a deficiency or absence of vitamines in the diet. Scurvy has also been stigmatized as probably due to an insufficiency of vitamines, and many are inclined to the belief that rickets may also be a deficiency disease. There is no doubt that the presence of vitamines in a diet is essential to the preservation of good health. The mortality from Salonica fever is believed to be greatly increased by the lowering of the patient's resisting powers and it seems not unlikely that McWalter is correct in attributing the severity of this fever to an insufficiency of the vitamine element of the food.

Educational Menus.

The medical profession has been described as being the only altruistic one in the world, that is, it is constantly endeavoring to deprive itself of its means of livelihood. When preventive medicine has achieved its final victory, the family physician can take in his shingle and bring up his children to be wireless operators or aviators. We are of course a long way from this millennium, but there is no doubt that the public is becoming better educated in health matters. Such terms as bacillus, salvarsan, and the calorie are mentioned in the best society now. For centuries mankind has dimly realized that the average individual eats too much and many aphorisms have gathered about the subject, as "Man lives on one-third of what he eats, the doctor lives on the other two-thirds," and "Leave the table always feeling that you could have eaten more." It is only comparatively recently, however, that the exact requirements of the human machine has been estimated with an arbitrary unit, the calorie, as a standard. The next step will be the familiarization of the lay public with the caloric value of various foods. A move in this direction has already been taken by the Public Health Department of New York City which furnishes educational menus to its employees at its lunch-room at headquarters. The menu cards are ruled vertically into five parts containing respectively the name of the food, its price, the quantity in a single order, the number of calories, and the protein content. Thus we have a glass of milk: four cents, seven ounces, 160 calories, seven grams of protein. Apple pie, five cents, one-sixth of a pie, 300 calories, four grams of protein. To be sure it would seem better to use the metric system all the way through if it is to be used at all, but this is of small moment. The important fact is that these employees can eat intelligently (if they wish to do so), something of which Americans are notoriously incapable, according to the Continental belief. When this custom is extended to private dinner parties we shall begin to realize its full benefit as an aid to conversation, as well as its possibilities as a guide to correct methods of living.

News of the Week.

The Poliomyelitis Epidemic.—The decline in the epidemic of poliomyelitis, though perhaps not quite so marked as was hoped, has continued steadily. The death rate from the disease has risen during the last two weeks somewhat alarmingly. For the week ending September 9 there were reported 351 new cases and 132 deaths, as compared with 477 cases and 157 deaths for the previous week. The total number of cases to September 9 was 8486, with 2100 deaths. It is estimated that the total cost of the epidemic will be about $1,000,000. The surgeons of the United States Public Health Service, who have been issuing certificates to persons leaving New York for interstate travel, have discontinued this service. The call for immune serums from persons who have recovered from the disease has met with a satisfactory response, and up to September 9 seven gallons of blood had been drawn, yielding three gallons of serum. The supply has not yet, however, been sufficient to meet the demand. An outbreak of the disease has been reported among the Crow Indians on the reservation near Billings, Mont., sixteen cases having appeared up to September 6. The openings of Williams College, Rutgers College, Amherst College, and Wellesley College have been postponed, in most cases until after the first of October, because of the prevalence of the disease. In New York State outside of New York City 2,575 cases, with 271 deaths, had occurred up to September 9. Commissioner of Health Emerson spoke before the League of American Municipalities in Newark on September 7, on the subject of infantile paralysis, reviewing the history of the present epidemic and the steps which had been taken by the Department of Health in the attempt to control it.

Poliomyelitis, Ptomaine Poisoning, and Sour-Grass Soup.—A writer in one of the New York newspapers has recently advanced the theory that the epidemic of infantile paralysis is due to the eating of spoiled food, and that many of the so-called poliomyelitis cases are merely cases of ptomaine poisoning. This is denied by the Health

Commissioner, who says that in the present epidemic very few wrong diagnoses have been made, but that on the other hand the diagnosis of ptomaine poisoning often is wrongly made. It is stated that several cases of illness occurring in the East Side of the city and reported as ptomaine poisoning were on investigation found to be due to indulgence in sour-grass soup. This is prepared from sour-grass, a species of sorrel, otherwise known as "qchav" or "schav" leaves, which are rich in oxalic acid salts. The soup is a common dish in some of the East Side restaurants. In one restaurant visited by the Health Department inspector it was found that the method of preparation was as follows: The leaves were stripped from the stalks and well washed, the washings being thrown away; they were then soaked over night in cold water, and later boiled for fifteen minutes. This water also was thrown out. The leaves were then boiled for the second time, eggs and cream were added and the dish was ready to serve. Chemical analysis of the finished soup showed about 10 grains of oxalic acid to the pint.

Sick Rate on Border.—Statistical reports from medical officers in charge of troops on the Mexican border show that the percentage of sick among both regular troops and National Guardsmen was less than 2.5 per 100 for the week ending September 2. During that time six deaths occurred. The army medical officers regard the condition as unusually satisfactory for this season of the year.

Typhus in Mexico.—An epidemic of typhus fever is reported in the State of Zacatecas, Mexico. Physicians are being sent from Mexico City to fight the disease and precautions are being taken to prevent its spread to other parts of the republic.

War on Mosquitos.—The Princeton, N. J., Board of Health is planning a general clean-up movement for the extermination of mosquitos in the marsh lands near Lake Carnegie. Thousands of loads of fill have been dumped on the low ground and the land has been graded so that excess water will drain off into the lake. It is estimated that between $5,000 and $10,000 will be needed for the work.

Is Whiskey a Medicine?—The question how to meet demands for whiskey and brandy for medicinal purposes was discussed at the American Pharmaceutical Association in session at Atlantic City last week. Both have been deleted in the new pharmacopœia of the United States, and it was feared that this action might prevent the sale of all alcoholic stimulants in drug stores.

Gift to Charities.—In lieu of rent for Shadow Lawn, the summer White House at Long Branch, N. J., President Wilson has sent to the committee in charge his personal check for $2,500, the money to be distributed among charitable institutions in Monmouth County. This was the stipulation made by the President when he agreed to accept Shadow Lawn as a residence without rent.

Typhoid Epidemic.—Altoona, Pa., is threatened with an epidemic of typhoid fever, six deaths having occurred to September 8. The State Department of Health has inspected the city's watershed and has found evidence of serious contamination. The city has been placarded with warnings that water for all purposes should be boiled as a precautionary measure. It has been predicted that five hundred cases may occur before the epidemic reaches its height.

Memorial to Poliomyelitis Victim.—The Philadelphia Department of Health has begun plans for the erection of a memorial to Dr. Earle C. Peck, who, as reported in the obituary column, died last week from poliomyelitis contracted in the course of his service as chief resident physician in one of the Philadelphia hospitals in charge of infantile paralysis cases.

Strike in Hospital.—The nurses and students at the Philippine General Hospital, Manila, went on strike on August 31, as a protest against the discipline of the hospital, and on the following day the disturbances became so serious that it was necessary to call out American reserves.

Dr. Julius E. Foehrenbach has been appointed assistant bacteriologist in the Department of Public Health and Charities of Philadelphia.

Civil Service Examinations.—The Civil Service Commission of the State of New York announces examinations on September 30, 1916, for the purpose of filling vacancies in the following positions:

Laboratory assistant in bacteriology, State Department of Health. Men and women, $720 to $1,200 a year. Only candidates who have satisfactorily completed a systematic course in bacteriology and have had not less than eight months' practical experience will be accepted. The examination will cover the technical procedures used in the study of pathogenic bacteria, and immunity, and the standard methods used in the examination of milk, water, sewage, air, and soil.

Laboratory apprentice, State Department of Health, $600 to $720. Candidates must have a collegiate education or its equivalent. A knowledge of bacteriology and practical laboratory experience are desirable but not essential.

Assistant physician, regular or homeopathic, in State hospitals and other State and county institutions. Salary in State hospital $1,200 to $1,600 with maintenance. Open to men and women who are licensed medical practitioners in New York State, and graduates of a registered medical school, and who have had since graduation one year's experience on the resident medical staff of a general hospital or as medical interne or clinical assistant in a state hospital or institution, or have been engaged for three consecutive years in the practice of medicine.

Woman physician, regular or homeopathic, in State hospitals and institutions. Salary $1,000 to $1,500 a year and maintenance. Candidates must be licensed medical practitioners in New York State and have had at least one year's experience on the medical staff of a hospital or three years' experience in the practice of medicine.

Further details and application blanks will be furnished, until September 18, by the State Civil Service Commission, Albany, N. Y.

Sentenced for Fake Cure.—The New York City Department of Health has secured the conviction of an imposter in this city on the charge of selling as a cure for infantile paralysis a bag of cedar shavings and advertising this in the newspapers as a cure. In the Court of General Sessions last week the man was sentenced to serve thirty days in jail and pay a fine of $250. The bags were similar to those in which tobacco is sold and were labeled with a red cross and "Infantile Protector" in red ink. They were sold at ten cents each and were said to confer immunity when worn about the neck.

U. S. Cruiser to Transport Supplies.—The medical supplies for the hospitals in Palestine, which, ever since an embargo was put on shipments to that part of the world, have been in charge of the American Consul at Alexandria, will soon be forwarded to their destination on the U. S. cruiser

Des Moines, by order of the Secretary of the Navy. The need for medicines and medical supplies in the districts about Jaffa and Jerusalem has become very great, and for this reason the Allies at the instance of the Department of State have consented to the forwarding of the detained shipment.

Typhus Fever Germ.—A newspaper dispatch from Berlin recently contained the announcement of the discovery of the germ of spotted typhus by Dr. Eugen Czernel, bacteriologist, at Budapest.

Portraits for Hospital.—Through the generosity of Dr. Howard Kelly and Mr. Blanchard Randall, the Johns Hopkins Hospital, Baltimore, is now in the possession of a collection of portraits of medical men, giving it one of the finest portrait galleries of the sort in the world. The collection, which is valued at $100,000, consists of forty-eight portraits, some of which date back to the early part of the sixteenth century.

Charitable Bequest.—By the will of the late C. Cresson Wistar of Philadelphia, the sum of $2,000 is bequeathed in trust to the Howard Hospital of that city.

Rebuilding City Institutions.—The Commissioner of Charities of New York City has had prepared plans, involving an expenditure of $1,400,000, for the rebuilding of the institutions on Randall's Island and the enlarging of Sea View Hospital on Staten Island. When the improvements at Sea View are completed its capacity will be increased from 1,000 to 2,000 patients. The buildings on Randall's Island, some of which were put up in 1848, are all of wood and brick and will be replaced as far as possible with fireproof structures.

Obituary Notes.—Dr. Earle Curtiss Peck of Philadelphia, a graduate of the Jefferson Medical College, Philadelphia, in 1914, interne at the Germantown Dispensary and Hospital, died at the hospital, after a short illness, from poliomyelitis contracted in the course of duty, on September 5, aged 25 years.

Dr. Sterling Barrows, formerly of Amherst, Mass., a graduate of the College of Physicians and Surgeons, New York, in 1906, and a member of the Massachusetts and Hampshire District Medical Societies, died at his summer home in Worthington, Mass., after a long illness, on August 16, aged 36 years.

Dr. Joseph Logue Lockary of Boston, a graduate of McGill University, Medical Faculty, Montreal, in 1897, formerly assistant professor of obstetrics at Tufts College Medical School, Boston, and a member of the American Medical Association and the Massachusetts Medical Society, died, after a short illness, on August 13, aged 46 years.

Dr. Albert Currier Buswell of Epping, N. H., a graduate of the Medical School of Maine, Portland, in 1878, and a member of the New Hampshire and Rockingham County Medical Societies, died at his home, after a long illness, on August 12, aged 63 years.

Dr. James H. McLaughlin of Sutter Creek, Cal., a graduate of the Kentucky School of Medicine, Louisville, in 1891, and a member of the Medical Society of the State of California and the Amador County Medical Society, died in Stockton, Cal., on August 22, aged 54 years.

Dr. Michael Lewinski of New York died at his home on September 1, aged 54 years.

Dr. Stacey Watkins Boyle, formerly of Middleburg, Vt., a graduate of the New York Homeopathic Medical College and Flower Hospital, New York, in 1908, died suddenly at Panama, on August 20, aged 39 years.

Dr. William Henry Baker of Lynn, Mass., a graduate of the Hahnemann Medical College and Hospital of Philadelphia, in 1880, died suddenly at his home on August 22, aged 72 years.

Dr. Edward L. Estabrook of Minneapolis, Minn., a graduate of the Long Island College Hospital, Brooklyn, N. Y., in 1878, died at the Corey Hill Hospital, Brookline, Mass., after a short illness, on August 20, aged 70 years.

Dr. M. J. Newberry of Lizella, Ga., a graduate of the Atlanta Medical College, Atlanta, Ga., in 1886, died at his home from paralysis, after a lingering illness, on August 27, aged 54 years.

Dr. John H. Roebuck died recently at Bethlehem, Pa., at the age of 76 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1865.

Dr. Clarence James Lockhart of Freedom, Pa., was killed by a disappointed patient on August 20, aged 28 years. He was a graduate of the Cleveland-Pulte Medical College in the class of 1912.

Obituary.

RUDOLPH H. VON EZDORF, M.D.,

UNITED STATES PUBLIC HEALTH SERVICE.

Dr. R. H. von Ezdorf, surgeon in the United States Public Health Service, and at the time of his death in charge of the United States Marine Hospital at New Orleans, La., died at Lincolnton, N. C., on September 8. He was born in Pennsylvania and was a graduate of the George Washington University Medical School, Washington, D. C., in the class of 1894, and entered the Public Health Service in 1898. Dr. von Ezdorf was widely known for his researches in yellow fever, typhoid fever, and particularly malaria, of which he had made a special study and on which he had written much in the Public Health Service Reports; he was also the author of the article on Malaria in the Reference Handbook of the Medical Sciences. He had at various times been in charge of the quarantine stations at Savannah, Mobile, New Orleans, and other places. He was a member of the Medical Association of the State of Alabama and of the American Medical Association.

Correspondence.

LIABILITY FOR PROFESSIONAL SERVICES RENDERED TO ANOTHER.

To the Editor of the Medical Record:

Sir:—The following letter from Mr. A. Frank Cowen may be of interest to your readers. I am forwarding it to you exactly as Mr. Cowen has written to me. I thought that perhaps it would be well for the protection of the profession if this decision and Mr. Cowen's instructions were published.

Samuel Lloyd, M.D.

12 West Fiftieth Street.

My dear Doctor:

In the belief that the medical journals have overlooked the importance of a comparatively recent decision of the Court of Appeals on the question of the liability of a person for professional services

rendered to a third party who is neither the wife, husband, nor minor child of that person, I am calling your attention to the same trusting that it will be of interest to you and to your colleagues in the profession.

The decision was rendered in the case of McGuire v. Hughes, 204 N. Y., 516. A physician was called upon by the defendant, a widow, to render professional services to her daughter, a married woman who was then living with her husband. At the time the physician was called into the case the patient was stopping at the defendant's residence. Without any definite understanding or without any inquiry as to who was to be responsible for the bill to be rendered, the physician proceeded on the theory, since the patient was the defendant's daughter and was being treated at home and that the request that she be treated had come from the defendant, it was all right for him to assume that she, the mother, was responsible for the bill.

In due course of time he rendered a bill to the mother and after payment was refused proceeded to bring suit. The case was eventually carried to the Court of Appeals at Albany. Throughout the litigation the physician made no pretense that there was any express promise or agreement on the part of the mother to pay for her daughter's treatment but instead relied on the facts in the case to raise an implied agreement on the mother's part to do so. The Court said as follows:

"The only question upon this appeal is whether the defendant came under any obligation to the plaintiff. That turns upon whether the law will imply a promise on her part to compensate him. If we might assume the existence of a moral obligation, that would not determine that a legal, or enforceable, obligation existed. The general rule, that where a person requests of another the performance of services, which are performed, the law implies a promise by the former to pay their reasonable value, has no application in the case of a physician, rendering professional services to a third person, if the relation to the patient of the person, who requests them, be not such as imports the legal obligation to provide them."

Now in the case before the Court there was no legal obligation on the part of the defendant to provide professional services for her daughter. She was not only over 21 years of age, but she was married and living with her husband.

The Court held further:

"The fact of a request to a physician to attend a patient is not, alone, sufficient for the inference of an agreement to pay for the services rendered (citing cases). We are, therefore, of the opinion that it should be taken as the rule of law, too well settled upon authority to be now questioned, that a physician, in the absence of a special contract, may recover upon an implied agreement to pay for his services *quantum meruit*, where they have been rendered at the request of the patient or of a person who, in the eye of the law, is regarded as being under a legal obligation to provide such professional services for the patient; such as a husband, wife, or the parent of a minor child."

From a reading of the decision, it becomes apparent that in a case similar to the above where the relation of parent, wife, or minor child does not exist so as to import a legal obligation for the payment of the physician's services, it is absolutely essential that an express promise to pay shall be clearly evidenced in order to sustain in the courts a claim for such services. A promise of this kind is best expressed in writing and I submit a short form that leaves nothing to the imagination but effectually binds the party executing the same.

Very sincerely yours,

A. FRANK COWEN.

Form.

This is to certify that I have this day engaged .....M.D., to render professional services for ..... and that I obligate myself to pay for the services so rendered.

Date.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

CITY MEDICAL REPORT—SHORTAGE OF RESIDENT MEDICAL OFFICERS AT VOLUNTARY HOSPITALS—LOSS OF MEDICAL OFFICERS AT THE FRONT—ST. JOHN'S AMBULANCE AND RED CROSS SOCIETIES.

LONDON, Aug. 17, 1916.

THE City of London medical officer has just issued his report for 1915. Referring in it to the evil of coal smoke he declares it cannot be satisfactorily dealt with by law until the enactments at present in force are amended. The dirt and discomfort continue, though in less degree than in former years. For this the enormous number of chimneys in surrounding "Greater London" are largely responsible. During 1914, with the concurrence of the Sanitary Committee, a critical examination of the air in the city was begun in conjunction with the Committee on Atmospheric Pollution, appointed by the International Exhibition of 1912. A large rain gauge placed in a convenient position was used to collect the rainwater from a known area. This rainwater containing the soot, grit and dust washed from the air was submitted to the public analyst. In the month of November the solids falling in the city were estimated at 58 tons, of which 35 tons were soluble. An observation has been made daily of the purity of the air by a new method. The amount of impurity at noon has varied from a mere trace up to 3 milligrams per cubic metre of air, including times when there has been a slight fog, but no dense fog has at present been tested.

The scarcity of resident medical officers in the voluntary hospitals has been discussed at one or two meetings lately, and there is an impression that it will become more acute with the progress of the war. As a result of inquiries at 50 hospitals, Mr. Courtney Buchanan reported a great excess of expenses. Where only two or three residents were required the vacancies were easily filled up, but where four or more were needed there was difficulty, and in some instances out-patient work had been restricted. General practitioners had in some instances been called to assist in other cases by lady doctors. The non-teaching hospitals, with salaries of £150 or £200, could not compete with the War Office, which offered twice as much, besides other attractions. Graduates of our Canadian and Australian schools had found occupation in this direction. In July, 1914, there were 104 resident medical officers in 26 London hospitals; now there are only 81. King Edward's Hospital Fund has made representations to the War Office, it being thought that some engaged in official positions might be transferred with advantage. More cooperation between the civil hospitals and the military authorities would probably be beneficial. The British Hospitals Association is collecting information as to the number and qualifications of men available for service, and arrangements could surely be completed for transferring officers from places over-supplied to positions where there is any deficiency.

The losses of medical officers in the present war are very heavy. In the Franco-Prussian War out

of 4962 German doctors with the army only 9 were killed and 69 wounded. In the present struggle up to Jan. 15, the German doctors killed numbered 56, the wounded, 216, and prisoners, 40, besides which 94 are missing, 29 have died of disease or wounds, 5 have met with accidents and 2 are sick, out of the total number of about 12,000 actually with the army, not including those in military hospitals. Besides these, 10,000 are employed in reserve hospitals, sanatoria, prisoners' camps and ambulance trains. Germany has some 32,000 members of the profession, so only about 8000 appear to be available for civil practice.

General Sir J. Maxwell has issued from headquarters (Irish command) an expression of his sincere appreciation of the services rendered in the late disturbances in Dublin by the medical, surgical and nursing staffs of the hospitals and especially to the gallantry of some nurses who exposed themselves to heavy fire in attending and removing the wounded. Further, to members of St. John's Ambulance and the Red Cross Societies, as well as many medical men and private individuals who gave assistance to the wounded or placed their houses at the disposal of the military for use as dressing stations. In numerous instances these services were rendered at considerable personal risk and under circumstances reflecting the greatest credit on those engaged in them.

OUR LETTER FROM ALASKA.

(From Our Regular Correspondent.)

IMPETIGO CONTAGIOSA AMONG THE NATIVE ESKIMO. SOME DIFFICULTIES IN COMBATING IT.

St. Michael, August 5, 1916.

Those readers who have followed these letters from Alaska have, we hope, gained a fair insight into the mode of life of the Eskimo in Northwestern Alaska. If so it will readily be appreciated that it is a very difficult proposition indeed to combat any form of epidemic disease among these poor, ignorant, superstitious, dirty people. Their bedclothing is usually composed of a few skins or dirty old blankets thrown on the floor, and their wearing apparel, too, is composed of skins, sometimes mixed with cloth garments. However, the Eskimo has usually but one outfit of clothing, and he wears that all the time, day and night. The children dress in the same way, even very small children. The babies often wear no form of diaper at all, and it is an interesting fact that the Eskimo children learn to use some form of commode at a very early age. Since they wear the same clothing day and night, rarely washing these clothes or themselves, and sleeping huddled together among these dirty bedclothes, epidemic diseases spread very rapidly among them and are very difficult to check. One cannot boil the bedclothing or the clothes they are wearing. They have but one set and nothing to use while these are being cleaned; besides furs cannot be boiled. Their houses, too, are as dirty in proportion as their clothing.

With the above conditions existing in the Native Village—which village is said to be one of the cleanest in Alaska—impetigo contagiosa appeared in an epidemic form among the children in April in 1916, and it soon gained great headway in the native school as well as in the village. The disease soon spread into the town of St. Michael, appearing in the school for white children as well as in isolated cases throughout the entire community. It was an easy proposition to handle the white children. They were isolated and their clothing was boiled or placed in the sun; the patients were treated, school visited, and search made for new cases.

An effective quarantine among Eskimos in an Eskimo village is impossible without armed enforcement, and the nature of this malady did not justify such drastic action. However, the village and native school were frequently searched for new cases. An out-patient dispensary was established at the schoolhouse where the native children were seen daily and treated. A roster was kept, entering new cases and discharging others when cured. If the native did not report for treatment, he was sent for and brought to the dispensary. Records were kept and the village plotted, showing where each infected house was. Isolation of infected children was attempted by talking to the mothers and fathers and explaining how the disease spreads; this undoubtedly did good though isolation could not be enforced; however, the "medicine man" was instructed in the beginning to keep his hands off or he would be put in jail.

There are 56 children in the village under the age of fifteen years and about 25 of them became infected with this disease. The lesions were principally upon the face and hands, but the trunk was often affected. Infection around the nails was common and a mixture of scabies and pediculosis with impetigo contagiosa was several times noted. The lesions were vesicopustular, with thin scabs, no infiltration or hyperemic surrounding zone; no itching and apparently no toxemia as the children seemed to feel well at all times; they were superficial and left no scars but a dark pigmentation was often noticed at the site of a former impetigo lesion. Several cases showed lesions on the scalp, and one an eruption in the mouth.

The treatment consisted in boiling the clothing wherever possible, scrubbing the body with warm water, tincture of green soap, and a brush and an application of mercurial ointment, sulphur ointment, and vaseline in equal parts. This was rubbed in well daily. The white children responded promptly, but it required about three months to suppress the epidemic in the Native Village. The continuance of this disease among the Eskimos was due to the fact that it was impossible to establish an effective quarantine, due to autoinoculation, and the transfer of infection through the medium of clothing and their dirty hands.

There was one house in the village where the infection persisted. Five children lived in this one-roomed house. Impetigo contagiosa was detected here at the beginning of the epidemic and remained for about three weeks after all other houses appeared free of it. One child named Hilma Otten who lived here and is about 7 years of age, was three times under treatment during the three months that this disease was present in the Native Village, being discharged as cured and readmitted to sick report. This illustrates the difficulty of treating such diseases among the Eskimos.

Although we do not know whence this infection came, how long it has been among the natives of this section, its cause, the details of its transmission or its exact status when apparently suppressed, it is believed to be but a question of a short time before there will be a reappearance of the disease among the natives of St. Michael.

1. Contact Points Between Tuberculosis and Syphilis. James A. Lyon.
2. Tuberculosis Carriers. Charles E. Perry.
3. What Constitutes Clinical Tuberculosis in Adults? George L. Schadt.

1. Contact Points Between Pulmonary Tuberculosis and Syphilis.—James A. Lyon, in order to test the supposition that a definite number of so-called tuberculosis patients would be found to possess definite pulmonary syphilitic lesions, tested 471 patients in the Rutland Sanatorium by the Wassermann test. Of these 430 were negative, 10 were doubtful, two were unsatisfactory, and 29, or six per cent., were positive. Of the 430 negative cases, 140 had incipient pulmonary tuberculosis, 105 of these had repeated negative sputum, and 35 had positive sputum. Of the moderately advanced cases there were 222, and of these 75 had negative sputum, and 149 had positive sputum. The remaining 68 were far advanced, and of these seven were negative and 61 had positive sputum. The sputum was negative in four and positive in two of the doubtful cases in the incipient stage; two had negative and two positive sputum in the moderately advanced stage. There were no doubtful cases in the far advanced stage of their pulmonary disease. A positive Wassermann was obtained in 10 incipient cases, and of these eight had negative sputum and two positive. In the moderately advanced stage, four had negative and 11 positive sputum. In the far advanced stage there were only four that gave a positive Wassermann, and in each instance the sputum was positive. From his experience the writer believes a careful inquiry should be made into all cases of pulmonary disease as to the possibility of a latent syphilitic infection, and, if there is a suspicion of syphilis, the search should not be abandoned in a case of pulmonary diseases with a positive or even a negative Wassermann without first having a careful radiograph taken of the lungs and the long bones. The presence of cavity signs in the lung and the expectoration of large amounts of sputum persistently negative to tubercle bacilli should always suggest pulmonary syphilis. If a positive reaction to tuberculin occurs in a given case of pulmonary disease with a marked positive Wassermann, it is difficult to make a correct diagnosis because the two diseases may coexist while the *x*-ray examination may not be of assistance.

3. What Constitutes Clinical Tuberculosis in Adults?—George L. Schadt emphasizes the belief that it is not only in the beginning cases of tuberculosis that we err in our diagnosis, but just as much in the diagnosis of the moderately advanced and advanced cases. He urges a consideration of the percentages of wrong diagnoses as cited by Ash and the fact that during only the past year a matter of 1.6 per cent. of the individuals entering the State sanatoria of Massachusetts were either non-tuberculous or not diagnosed. The responsibility is just as great in the diagnosis of the patient presenting with what seem to be all the necessary signs and symptoms for the diagnosis of advanced tuberculosis as in the doubtful case. The necessity of approaching the examination in these cases with a mind as free and unprejudiced by the history of cough or hemoptysis as is possible should be emphasized, remembering that almost any pathological condition in the pulmonary tract may simulate tuberculosis in every respect. Pottenger, in suggesting the consideration of the symptomatology from the etiological viewpoint, has made it easier to analyze the disease conditions. The essayist agrees with Lawrason Brown and others that the importance of physical examination in the diagnosis of pulmonary tuberculosis has been overemphasized in that symptoms are a better guide to activity than physical signs and that symptoms without physical signs demand treatment, and physical signs without symptoms require only careful watching. It does not seem possible or probable that we can ever outline a symptom complex of certain signs and certain symptoms and say that these signs and symptoms in every case mean tuberculosis. It seems rather that we must value each symptom and each sign for itself and in conjunction with other symptoms and signs, for every case is a different one and has a different complex. Though deeming that certain outstanding symptoms, such as hemoptysis, cough, elevated temperature, increased pulse, and emaciation are suspicious of infection, we are not qualified to say that this is a case of active tuberculosis in an adult without proper and due consideration to other factors present.

9. Graves's Disease. A Report of a Case with Post-operative Amblyopia. Chester Henry Keogh.

1. Pyorrhea Alveolaris.—John A. Roddy, Elmer H. Funk, and David W. Kramer state that if this disease did no more than interfere with mastication, it would be serious enough to deserve the attention that has been given it by the dental profession, but an indisputable mass of evidence has accumulated which shows that the complications of this disease develop in portions of the body remote from the head, and seriously injure or destroy important organs. Their conclusions are that: (1) Pyorrhea Alveolaris is not a specific disease; its chief etiological factors are (a) an excessive bacterial flora of the mouth; (b) deviations from the normal of the afflicted tissues brought about by certain diseases. (2) Oral sepsis is the first stage of pyorrhea; the etiology of both is the same. (3) Pyorrhea can be prevented by regular cleansing of the mouth and teeth. (4) The detection of all the etiological factors in the majority of the cases of pyorrhea requires a thorough dental and medical examination. Whenever possible an *x*-ray examination should be made. (5) Acute recurrent gingivitis or chronic gingivitis or a persistent excessive bacterial flora of the mouth is a clinical sign of the disease. (6) Systemic complications are rare in the early stages and frequent in the late stages. (7) Coincident systemic diseases are frequently associated with pyorrhea. (8) There are no specific methods of treatment. (9) The three indispensable factors in the treatment are: (a) Training the patient regularly to cleanse the mouth and teeth; (b) the institution of whatever dental treatment may be indicated; (c) medical treatment of coexisting systemic disturbances or disease. (10) Emetin may be well employed as an adjunct on the principle that it will de no harm and may possibly in some cases be beneficial. (11) When infectious systemic complications exist, an autogenous vaccine is indicated and even in uncomplicated cases will at times accelerate improvement.

4. The Syndrome of Asthenia of Mental Origin.—

Meyer Solomon states that worry over somatic or external factors may lead to insomnia and the syndrome of asthenia. Worry concerning these symptoms may now take the place of the original causative factor, the patient as a rule not appreciating the relationship. This may be the starting point of true psychoneurotic states. Once the symptoms have appeared there is a veritable vicious cycle—the emotionalism with suggestion increasing the symptoms, in degree or number or both, and the accompanying symptoms increasing the emotionalism and suggestibility. The diagnosis is easy, with the aid of the history and the exclusion of physical disease as the primary cause. The differentiation, however, must be made between this form of asthenia and tuberculosis, arteriosclerosis, syphilis, etc. The prognosis in uncomplicated cases is most favorable, treatment being simple and results prompt. The mental factor should be thought of, investigated, and weighed in every case of the asthenic syndrome, especially when no apparent cause exists. Insomnia is most potent in producing symptoms and must be boldly and unhesitatingly treated by drugs and otherwise. In these cases successful treatment means that a psychoneurosis or minor psychosis may frequently be aborted.

6. **Spasmus Nutans.** — Murray B. Gordon reports three cases of this rather unusual condition out of 4,000 general cases which have come under his personal observation at the Polhemus Memorial Clinic. He says that spasmus nutans is a rare functional neurosis found in children, which consists of an almost continual nodding or shaking of the head. In some cases there is a rotary movement of the neck. Generally there are no other rhythmic movements or other phenomena of nervous irritability, though in some cases, as in one of those reported, there may be an accompanying spasm of an arm or a leg. The mentality of the child is not impaired. During the attack there is no loss of consciousness. In many instances attacks are brought on by the child turning its head, or concentrating its attention, in an endeavor to look upon a particular object, or in a certain direction. In the majority of cases reported, nystagmus has been associated with the spasm of the head. Some observers hold that nystagmus is present in every case of spasmus nutants, and that their contentions can be proved if every case is seen long enough and observed minutely. In two of the cases in this series nystagmus was not observed. This condition is in no way connected with or related to epilepsy, tetany or any tetanoid hyerirritability of the nervous system. It is insidious in its onset, and may not be noticed in the first stages. The course of the condition varies; the longest period in which it persisted was reported to have been two years. The treatment should be directed to the correction of malnutrition and faulty hygiene. Thyroid extract has been found efficacious. This may be given alone or in conjunction with calcium lactate. The elixir glycerophosphates of lime and soda may be given alternately with the thyroid.

7. **Primary Perithelial Sarcoma of Spermatic Cord.**— Adolph Brand reports the case of a young man, 29 years of age, who had suffered a year previously from urethritis followed by a hemorrhagic and suppurative orchitis. He was in apparently good health for during this year when he returned with a mass in the left side of the scrotum. A diagnosis of tumor of the spermatic cord was made and the growth removed. This was found to be a perithelial sarcoma of the spermic cord. Brand states that very little is known of the etiology of spermic cord neoplasms. Recent injuries are credited with being the causative factors in a small percentage of cases, and it is denied that venereal disease plays a provocative role. It is stated by many authors that neoplasms of the spermic cord usually develop secondarily to such growths in the testicle, but it is conceded by some that the primary origin of the tumor may be within the cord itself. In this case a thorough examination of the removed testicle, by a pathologist of unquestioned ability, failed to show evidence of malignancy, and it must be argued that in this instance the spermic cord was the primary seat of the growth. Another point in this case is the etiology. Since recent injuries are looked upon as the causative factors in the production of tumors of the spermatic cord in 25 per cent. of the cases, the question may be raised whether the suppurative process in the testicle and the surgical intervention acted the rôle of trauma in the subsequent development of the neoplasm of the spermatic cord.

1. **Ringworm of the Hands and Feet.**—Oliver S. Ormsby and James Herbert Mitchell present an analysis of 65 cases seen in the routine of private practice who did not present the ordinary clinical symptoms of ringworm of the body, but are examples of what is ordinarily termed dyshidrosis or eczema of the vesicular-vesiculo pustular or intertriginous type. The diagnosis depends on the microscopical examination of the tissues. All vesicular or desquammating areas of the interdigital or volar surfaces of the hands and feet should be carefully examined for the presence of fungi. Eczematoid and dyshidrotic lesions of the volar surfaces due to myotic infection are much more common, at least in the Middle West, than the number of reported cases indicates. The disorder occurs much more frequently in men than in women, on the feet than on the hands, and more frequently in the warm and damp than in the cold and dry season. The essential lesion is a deep-seated vesicle, in the roof of which mycelial threads may be found. The areas affected in the order of frequency are the fourth interspace of the foot, the plantar surface of the arch, and over the tuberosity of the fifth metatarsus. The disorder frequently follows or precedes eczema marginatum, and is due in many cases to the same organism. The pathogenic organism may remain dormant in the cutaneous folds of the feet throughout the winter months. With the advent of warm weather an acute attack of vesication, desquammation, and maceration may occur. The treatment included the use of three preparations. In the severe cases of eczematoisdermatitis, a preliminary soothing treatment of naftalan, combined with zinc oxide and starch, was used. This was followed by 5 per cent. chrysobarin in traumaticin which is painted on until a good reaction occurs. Five daily applications were usually given. In

another series of cases an ointment containing two parts of salicylic acid and four parts of benzoic acid in 30 parts of ointment base were used. This was applied daily over several weeks.

2. **The Effect of Potassium Iodid on the Luetin Reaction.**—John A. Kolmer, Toitsu Matsunami, and Stuart Broadwell have been studying the effects of the iodids, bromids, chlorids, ether, chloroform, and other drugs on the luetin, tuberculin, and other skin reactions. The results with the iodids have proved definite and confirmed Sherrick's observations in practically every particular. The study warrants the following conclusions: 1. Well marked positive luetin reactions were observed among a group of healthy nonsyphilitic persons following the administration of potassium iodid. 2. Similar results were observed among nonsyphilitic persons suffering with various other diseases. 3. Somewhat severe reactions were observed following the intracutaneous injection of 0.1 c.c. of 0.5 per cent. agar-agar. 4. The strongest reactions were observed when the luetin was injected during or immediately after the ingestion of potassium iodid. 5. Positive luetin reactions were observed among normal nonsyphilitic persons as late as one month after the ingestion of large doses of potassium iodid. 6. In some instances the administration of potassium iodid caused the site of a former luetin injection to develop inflammatory phenomena progressive to pustulation. 7. Similar but less marked reactions to luetin and agar ware observed among guinea-pigs and rabbits following the oral administration of potassium iodid. 8. Accordingly, a positive luetin skin test has little value in the diagnosis of syphilis among persons who are taking or have recently taken potassium iodid. The amount of iodid capable of producing these reactions varies considerably; also the length of time following the ingestion of iodid when this reaction to luetin may follow. For these reasons physicians should very carefully rule out the possible influence of iodid before conducting the luetin skin test.

6. **The Results of Treatment in Arterial Hypertension Due to or Associated with Syphilis.**—Louis A. Levison has collected a group of 18 cases in which syphilis and hypertension were associated of which he has made a careful study, more particularly with reference to associated kidney lesions. He concludes that anti-syphilitic treatment is not expected to reduce the high blood pressure in syphilitics who have also arterial hypertension. Occasional reductions in the blood pressure, however, do take place in such cases. The association of arterial hypertension with syphilis does not contraindicate the treatment of the latter. The careful use of mercury and salvarsan has not had bad results on kidneys damaged by arterial disease.

7. **The Intensive Treatment of Syphilis.** — Lloyd Thompson reviews evidence as to the efficacy of the three syphilitic remedies and states that with this evidence the logical method of treating this disease is to administer mercury and salvarsan as intensively as the patient can tolerate in all cases, and iodin in some form where indicated. He has been able to reduce a four plus Wassermann to a negative which remained negative from one to six weeks with intramuscular injections of mercuric benzoate or intravenous injections of mercuric chlorid. It is the opinion of the writer that all cases of syphilis of the central nervous system should have intraspinal medication. For these injections he employs a method which is a combination of those described by Ogilvie and Wile. This consists in the withdrawal of 10 c.c. of blood by venipuncture and centrifuging it at once. One c.c. of this clear serum is removed and placed in a sterile test tube. The salvarsan is then prepared by dissolving in water, neutralizing, and diluting so that each 0.1 gm. is diluted to 40 c.c. One c.c., the dose usually required, is placed in the hemostat 37.5°C. for forty-five minutes. It is then removed and placed in a water bath at 55°C. for thirty minutes. The intraspinal injection should be made as soon as possible after the serum is prepared. The injection is made in the arachnoid space, the skin having first been infiltrated with 5 per cent. novocain. When about 15 c.c. of spinal fluid have been collected, one or two c.c. of 5 per cent. novocain are added and thoroughly mixed with the fluid which is allowed to run back into the spinal canal. After three minutes the fluid is again allowed to flow into the syringe and the salvarsanized serum added and injected. By using the novocain as described for both the salvarsanized serum and the mercurialized serum, the pains in the legs and back which so frequently follow these injections are eliminated to a great extent. Much has been written and said with regard to the wonderful cures of syphilis which have been affected at the great watering places of the world. It does not seem that the waters of these springs possess any specific value in the treatment of syphilis; the benefit is found in the pleasant surroundings, outdoor exercise, regularity of treatment, and the fact that the patient makes a business of getting well. It is a fact, however, that most patients bathing daily in the waters can tolerate more mercury without untoward effects than those not bathing.

11. **Lumbar Puncture for the Relief of Convulsions in Puerperal Eclampsia: Report of Two Cases.**—W. T. Wilson says he used lumbar puncture in these cases because he had seen convulsions controlled in his cases of cerebrospinal meningitis by drawing the fluid from the spinal canal before injecting serum. In both of the cases reported the patients had had over twenty convulsions and this procedure was followed by recovery. Lumbar puncture is a treatment only for the convulsions of eclampsia and not for the toxemia of pregnancy. However, with the convulsions controlled one is in a better position to treat the toxemia. Puncture seems to be indicated in those cases in which the convulsions are severe and frequent. It does not interfere with other forms of treatment for the disease, and proper treatment should be instituted as soon as the convulsions are controlled.

1. The Effects of Trinitro-Toluene on Women Workers. — Agnes Livingstone-Learmonth and Barbara Martin Cunningham have made careful observations of the symptoms complained of by women working on trinitro-toluene in the munition factories in which they have been acting as medical officers. They are convinced that the frequency with which these symptoms occur among workers cannot be a mere coincidence and must point to irritation by and absorption of some toxic product of the explosive used. The irritative symptoms described are referred to the respiratory tract, the alimentary tract, and the skin. The toxic symptoms include digestive, circulatory, cerebral, and special symptoms. From their observations they are convinced that the careful selection of workers is of the greatest importance and that women inclined to be anemic, those that have had liver or gastric trouble, those who sweat freely, those who have had chest trouble, those even slightly addicted to alcohol, and persons of lowered vitality from fatigue, malnutrition, etc., should be excluded from this kind of work. No person under 21 or over 40 years of age should be employed on trinitro-tuolene. Workers should not be employed more than twelve weeks continuously and not too long daily. A routine weekly examination of all these workers is essential and any that show signs of fatigue or toxemia should be taken off the work. If respirators are worn they should be impregnated with some alkaline antidote.

3. The Treatment of Infected Suppurating War Wounds.—Rutherford Morison described a simple method of treating suppurating war wounds which he has developed which consists in covering the wound and surrounding area with gauze wrung out of 1:20 carbolic acid, opening the wound freely, cleansing the cavity with dry sterile gauze, removing foreign bodies, mopping the wound and surrounding skin with methylated spirit, and then filling up the whole wound with a paste made of bismuth subnitrate, one ounce; iodoform, two ounces, and paraffin liq. q.s., to make a thick paste. For this preparation the writer suggests the name "Bipp." This dressing requires no change for days or weeks if the patient is free from pain and constitutional disturbance. A case of hernia cerebri is cited which healed readily with the employment of this procedure and it is claimed that under this treatment septic wounds heal by first intention with infrequent dressings and without drainage further than that allowed for through gaps left by interrupted sutures. Acute abscesses, opened, cleansed, filled with "Bipp" and closed by interrupted sutures can heal by first intention without further pus formation. It appears to be safe to plate compound fractures by adopting this method. Up to the present time no bad results have been observed after the employment of this treatment.

4. An Anomaly in the Widal Reaction. — A. F. S. Sladden calls attention to the fact that in following Dreyer's standard method of agglutination testing for suspect enteric cases in the lower dilutions a negative (inhibition) zone is frequently seen and that this is not peculiar to Dreyer's method. A feeble agglutinating power, if opposed by a well-marked inhibition zone, may only be visible over a short range of dilutions, and unless a large number of dilutions be tested the presence of agglutinin may be missed. In the experiments recorded the sera have been those of subjects inoculated against *B. typhosus* within 18 months. Addition of another serum, non-agglutinating to the bacillus under test, will increase the zone of inhibition. The presence of sodium chloride in the test augments but does not cause the negative zone. By using distilled water as a dilutent in place of normal saline the negative zone is diminished and the test rendered more delicate. The zone effect is exerted on all three members of the typhoid group but in varying degrees. Its extent tends to increase with the progress of the infection. No definite relationship between zone effect and clinical aspect is established, but the inhibition zone does not appear to be of unfavorable omen.

6. A Contribution to the Etiology of Epidemic Cerebrospinal Meningitis. — M. F. H. Gamble states that epidemic cerebrospinal meningitis was unknown in Victoria until May 27, 1916, when an outbreak originated in the military camp at Seymour. The organism causing the disease was practically identical with the gonococcus, a mutant form perhaps. A study of this epidemic gives convincing evidence that cerebrospinal meningitis in epidemic form may be a true gonorrheal inflammation of the arachnoid membrane of the brain and spinal cord, set up by the bites of infected pediculi corporis. During the winter the soldiers are reluctant to take the daily cold shower in the open and thus provide a soil on which the pediculi corporis thrive vigorously, and gonorrhea is always prevalent in a large training camp near a city. The real carriers of the meningitis were the lice ladened with gonococci or full of serum from a meningitis patient. The futility of prophylactic measures directed to the nasopharynx and the fact that no specific organism has been proven to be the cause of epidemic cerebrospinal meningitis, in the opinion of the author, lend plausibility to his theory as to the etiology of this epidemic.

2. Note on the Distant Effects of Rifle Bullets; with Special Reference to the Spinal Cord.—Judson S. Bury relates two cases which confirm the experience of the present war that the effects of high velocity bullets with rapid rotary spin are rarely limited to the parts through which it passes; as a rule there is evidence of either indirect or secondary lesions and sometimes of remote lesions. Of particular interest are the effects on the spinal cord of the passage of bullets in its immediate vicinity, in cases in which there is no evidence of direct injury to the cord. In some instances there was an impact of the bullet upon some portion of vertebra; in others, however, it was probable that the bullet did not strike the bone, but passed through the tissues outside of it. In both conditions the damage to the cord may be either severe or slight. In one of the cases cited the bullet entered near the top of the left shoulder and came out on the right side of the spine. The main points of interest in this case were the temporary incontinence of urine; the implication of some of the dorsal roots; the signs of a lesion of the right pyramidal tract, the fibers which convey impulses to the dorsoflexors of the ankle being chiefly affected. In the group of "spastic paralyses," cases are not uncommon in which no paralysis can be detected, the lesions of the upper neurones being represented clinically only by exaggeration of the deep reflexes. The explanation of this is difficult; it may be that a lesion too slight to produce paralysis that can

be detected is sufficient to cut off the cerebral impulses which are inhibitory to muscle tonus, when there will be overaction of the spinal centers which is probably, the author thinks, the result of the unopposed action of the cerebellum.

4. The Treatment of Convalescent Soldiers by Physical Means.—R. Tait McKenzie describes the work of the "command dépots to which are sent men for whom there is some hope of cure or improvement within a period of six months. Among those usually sent are cases of profound neurasthenia, the result of sleepless nights and arduous days; shock in all its forms—tremulous hands and tongue, stammering speech or deafness, persistent nightmares and fears by day; disorders of sensation, contractures, and paralyses; rapid and weak heart action, hearts that were overstrained and that are unable to sustain the effort of the lightest gymnastic exercise or the shortest march; rheumatism, real and unreal, in all its forms; lungs suffering from the bronchitis of gas poisoning, asthma, and even tuberculosis; profound debilities following typhoid fever, dysentery, and malaria, requiring months of good food, light duty, and progressive exercise to build them up. For all of these cases the treatment comes under what may be called physical therapy, electricity, hydrotherapy, massage, mechanotherapy, corrective exercises, physical training, and marching. The procedures employed in the various conditions are described in detail and it is pointed out that many cases of disordered heart action can be brought up to the full physical training but not into it. Several cases were brought up to this point three or four times and then had to be returned to lighter duty. Not more than 30 per cent. succeeded in passing into Class A. This same experience has been shared by some cases of shock, of bronchitis following exposure to gas, and cases of frostbite. An analysis of the classified cases sent out from Heaton Park up to date shows that nearly 50 per cent. have been returned fit for active service. About 15 per cent. have been sent to lines of communication abroad. About 15 per cent. have been sent to useful work of a sedentary nature at home, and over 20 per cent. have been discharged as permanently unfit, many of these being untreatable from the first. A fact which is not to be lost sight of, McKenzie says, is that even though these men may not be sent back as first class men their opportunities for a useful career in civil life after the war have been enormously increased.

5. Trismus During Serum Sickness (Septic Finger).—R. F. Bolt relates the case of an officer who pricked his finger while operating on a case of empyema. His temperature rose on the following day to 102° F., whereupon the finger was incised and a dose of 18 c.c. of antistreptococcus serum was administered. No antitetanic serum was injected. A week later an enlarged and tender gland was noticed in the right axilla and fourteen days after receiving the prick trismus developed. At this time an urticarial rash appeared over the arms, chest and abdomen. The possibility of the patient's symptoms being due to tetanus was seriously considered, but it was decided that he was already suffering from serum sickness and it was not advisable to give antitetanic serum. Under the administration of chloral hydrate and sodium salicylate the patient recovered. A careful review of the history of the wound made it seem unlikely that infection with the tetanus bacillus could have occurred, while the course of the symptoms and the rapid recovery, the author believed, made it very much more probable that the condition had been entirely due to the antistreptococcus serum.

Journal de Médecine de Bordeaux.

August, 1916.

Strangled Diaphragmatic Hernia; Laparotomy; Death.—Vitrac states that, evolution of symptoms in a case treated by him was almost pathognomonic. They comprised epigastric pain, acute thirst, painless retraction of the abdomen, precocious dyspnea unilateral thoracic symptoms, such as bulging of the chorax, tympany, etc. The squatting attitude is also quite characteristic. Let us suppose that we have a strangulation of doubtful origin. Laparotomy reveals a complex of empty and distended intestinal loops, so that we have to think of the possibility of more than one strangulation. In such a case we must always think of the possibility of a diaphragmatic hernia, and introduce the hand beneath the concavity of the diaphragm. A stop should be made to examine the thorax, if necessary by puncture. If the diagnosis is made a thoracotomy should be performed in order to liberate the strangled intestine. If reduction has been effected the lips of the hernia opening must be sutured. The prognosis depends on early diagnosis and early laparotomy. If simple suture cannot be effected a portion of lung tissue may be fixed into the opening.

Strophanthus and Strophanthin.—Mallié discusses at considerable length the physiological action, the clinical results, toxicity, indications, contraindications, modes of exhibition and posology of these substances. Before giving the drug the kidneys must be tested and blood pressure measured. All other medication must be suspended. Then on the first day 1/10 mgm. crystallized strophanthin should be injected into a vien in 10 c.c. freshly distilled water. The dose should be repeated on the second, third and fourth days. If the result is not as desired the treatment is suspended. The leading indication is cardiac insufficiency, either subacute or fatally progressive. In such cases strophanthin acts directly on the tonicity and contractility of the heart muscles. Given in a vein for this condition the drug action is more heroic than that of digitalis. In pulmonary asystole it is a better drug than the latter, overcoming the stasis more rapidly. In asystole of valvular origin the results obtained are not harmonious. On the other hand it may be invaluable in pure myocarditis, not as a functional stimulant of normal fibers but when the latter have become altered and delicate. Hence it is much used in France in the myocarditis of infectious fevers including pneumonia. It may succeed in a variety of conditions in which the rationale of its action is none too clear. Such successes are sometimes the exception. Here belong palpitation tachycardia, Graves' disease, old cardiac lesions with deeply altered myocardium, senile heart, etc. In certain well-known degenerations of the myocardium its use is contraindicated, as it is in angina pectoris, cardiorenal disease, arteriosclerosis, etc. Digitalis, as is well known, is a drug the employment of which is greatly subject to abuse and it is evident that strophanthus shares the same lot; all because the action and indications are not sufficiently studied.

Action of the Interossei Muscles.—Massé sums up an original study of these muscles as follows: One may consider that the action of the interossei is not limited to the fingers, as has always been held by the classic authors. They contribute almost wholly to the lateral movements of the metacarpals. Their insertions upon the articulations of the carpus, intermetacarpals, and metacarpophalangeals cause them to act as important, active ligaments to these articulations. They concur in maintaining the normal palmar concavity in two directions—length and breadth. This action therefore plays a rôle in the morphology of the hand.

Le Bulletin Médical.

August 12, 1916.

Primary Paludism in Salonica.—J. J. in a letter to the *Bulletin* gives information about the forms of malaria in this sphere of warfare which he thinks should prove of general interest. Some soldiers coming from France became contaminated on their arrival, diagnosis being determined in the bacteriological laboratories of the Eastern Army. A study of the blood shows three principal forms of parasite, the *Plasmodium vivax* (tertia benigna), *Plasmodium malariæ* (quartan), and *Plasmodium falciparum* (tertia maligna). Aside from certain regions affected with malaria, this so-called primary paludism is not seen in France to-day. It is unknown save in regions where the disease is endemic, like Salonica. It always appears a few days after the sting of an anopheles, the injury often being completely overlooked. At times it is masked as a febrile gastric disturbance, or even as a mild or severe typhoid. In such cases the patient's welfare is greatly prejudiced because he does not receive his quinine at the outset of the disease. These attacks of primary paludism are followed at an early date by a series of daily intermittent attacks, even in the absence of a reinfection. These attacks are not as cleanly defined as frank outbreaks of secondary paludism. They appear in periods of 5 or 6 days each, whatever the intensity of the treatment. A remission then occurs and the attacks reappear about every 12 days. If the patient has not been treated at all, or treated insufficiently, anemia appears, followed by enlargement of the spleen, and may pass on to a true cachexia with anasarca or simple edema of the legs and face, oliguria, palpitation, anorexia, diarrhea, apathy, and torpor. If such a patient is stung at any time by a fresh mosquito, the tendency is toward a continued fever.

Responsibility of the Army to the Civil Population When All Medical Supplies Have Been Commandeered.—A. M. writes to the *Bulletin*, referring to several recent articles on the subject. The lot of the rural dweller is particularly severe and the writer concerns himself solely with this aspect of the case problem. The countryman is deprived of the services of the better class of physicians, and must depend often upon a class of men who under normal conditions would have little to do. When a well qualified practitioner finds himself in such a situation, his difficulties are almost insuperable, if he is ignorant of the ways of the peasant, who, slovenly and indifferent, does not send for him until after the disease has a good start. The speech of the peasant is so full of local idioms, which vary even within small distances, that it becomes almost unintelligible. For example, a Paris physician assigned to practice in a certain sector remote from the metropolis, was summoned to attend a child who had been coughing for a month. He was informed that the child had been suffering from some affection with an unfamiliar name which turned out to be measles.

Le Caducée.

August 15, 1916.

Case of Anterior Spinal General Paralysis in a Soldier Due to Malaria.—Blin and Kernéis relate the case which they ascribed to a malarial infection. The patient, aged 20, had a good personal history. As an officer of the Senegalese he left Bordeaux for Africa and developed malaria during the 18 days he had spent in the tropics, probably because on one night he slept without protection against mosquitos. Interned in the nearest hospital the severe symptoms of the attack gave way to quinine, but at this juncture a severe dysentery developed but soon yielded to treatment. He continued to have mild febrile attacks as brief intervals, hardly severe enough to incapacitate him, but soon was seized with a very sharp attack of chills, fever and sweating which after three hours left him prostrated. The next day the fever returned and after the seizure the patient was found to be paralyzed. The entire lower extremities were stricken *en masse*, and the upper extremities progressively. On the next day the muscles of the face and trunk became paralyzed. Within the next 24 hours speech and swallowing became embarassed. The lips and jaws and eye muscles were not involved, nor were the sphincters, while sensibility was intact. The paralyses were followed by a certain amount of muscular atrophy which later attacked most of the voluntary muscles. An intercurrent attack of orchitis was without apparent cause. Gradually there was noted a return of power to some of the muscles—in general those last to be attacked, and despite the muscular atrophy a considerable restoration of function was noted elsewhere, and the reflexes which had been totally abolished began to reappear. The treatment had consisted of hypodermics of quinine and large doses of potassium iodide. Returning to France he eventually recovered completely. In this case a malarial polyneuritis could be excluded. The condition resembled anterior poliomyelitis in many ways and in fact was regarded as this disease, but due to malarial infection of the nerve cells of the anterior horns of the cord.

La Presse Médicale.

August 10, 1916

The Cardiac Rhythm in the Fighting Soldier.—Binet states that numerous peculiar modifications of cardiac rhythm have been noted in troops and their relatives as well. Those who have near relatives at the front or whose status in life has been inverted by the war, suffer from constant tachycardia, from 90 to 120, with inversion of the oculocardiac reflex. Those actually at the front show a much greater variety of pulse, due to the operation of various distinct causes. From mere extreme fatigue we see all the manifestations of asystole, with a small, filiform pulse, or perhaps paroxysmal tachycardia, or tachycardia with anhythmia or bradycardia (6 or 7 per cent. may show the latter alone). The state of suppression the emotions of warfare, as when men force themselves to be calm in a bombardment, is not accompanied by arrhythmia but bradycardia frequently follows a heavy, sudden explosion. When the sympathetic is chiefly involved acceleration of the heart beat is seen, and indicates that the soldier is naturally emotional and not very strong of heart. Emotional tachycardia is perhaps due to overproduction of thyroidin, especially when it becomes permanent. Another factor appears in the wounded, namely traumatic shock which should be largely psychical in nature. In some cases we see commotion without traumatism. In traumatic shock, much depends on the character of the wound, whether it is very painful or attended by much hemorrhage; and on the seat of the injury. Tachycardia commonly follows any wound in the chest. On the contrary slowing of the pulse is seen in cranial wounds. One who is shocked physically by an explosion may show tachy- or bradycardia, according as his sympathetic nerves or vagus react most strongly. Among aviators a rapid ascent or descent tends to lower the frequency of the pulse. In other words, so-called aviators' disease appears to depend on a functional disturbance of the vagus.

Insurance Medicine.

Respiratory Symptoms in Heart Disease.—Dr. J. S. Lankford says that one of the earliest symptoms of important disease of the heart is undue shortness of breath on exertion. It may be the sole symptom causing the patient to seek advice and the question must be determined whether it is simple or serious, for it may be the beginning of the gravest myocardial or other cardiac disease, or may be due to less important conditions. It occurs in unimportant vague disturbances, such as sinus arrhythmia, transient indigestion, and various irritable conditions of the nervous system. It may occur in a sound heart, which is out of proportion to the body in size. We occasionally find a man normal in all respects except that the heart is too small. If a man is perfectly free from all indication of disease, but is inclined to shortness of breath on exertion, his heart is probably too small for his body. This condition is especially likely to result from that form of infection in children which is generally characterized, "growing pains." It occurs also, in repeated infections of other kinds, especially in the throat. The heart may not have been inflamed, but has been sufficiently embarrassed in nourishing itself to prevent the proper growth. A like limitation of growth occurs in the young inveterate cigarette smoker. A similar condition exists where a man weighs 130 pounds at 25 years of age and 230 at the age of 40. His heart has attained the growth necessary for a small body and is always tired from carrying such a heavy burden, and yet it may be a sound heart. There is grave danger of high blood pressure and a breakdown in the heart or kidneys, in this kind of case after the age of 45, because the heart cannot nourish itself properly and do the work of such a heavy body. These patients should be cautioned to live rigidly within the reserve power of the heart, to avoid stimulants, to drink water sparingly, and especially should they be directed to steer clear of excess in starches and sugars, the fat producers. It is better for them to take the chances of an albuminous diet than to put on more flesh. There is here some disturbance of the internal secretions not yet fully understood, but it is probable that the thyroid and other ductless glands are involved in the accumulation of flesh. No insurance applicant requires a more thorough examination than the heavy-weight. Serious organic disease may be confused when testing by means of exercise and the manometer, with a poisoned heart, but the absence of the usual signs and the collateral symptoms of poisoned heart, as autointoxication, marked indicanuria albuminuria, or some infectious condition, especially from the teeth, will point the way to the truth, the blood pressure is low and the pulse pressure very limited. This condition may be relieved by treatment and the heart saved from organic disease. In very grave heart disease of any kind, there is always shortness of breath on exercise and sometimes air hunger on exertion. In nearly all cases there is inability to stop breathing, a very significant symptom. Continuous labored breathing is also characteristic of serious heart disease, indicating an exhausted myocardium. Unconscious, rapid breathing is a symptom that is often overlooked both in chronic heart disease and in heart complication in infectious diseases of various kinds, especially typhoid fever and tuberculosis. Aortic insufficiency is always attended by embarrassed breathing in some form. Mitral insufficiency is accompanied by short breathing on exercise or it may be continuous if the myocardium has become involved, dilatation taken place, or dropsy occurred.

Mitral stenosis is usually accompanied by shortness of breath on exercise, which may become a dominant characteristic late in the disease when the myocardium is in serious trouble. Angina pectoris leads to great embarrassment of breathing on account of pain in the intercostal muscles and the nerves of the skin over the region of the heart, on the inside of the left arm and sometimes the right, and down back of the left ear. Of all the distressing conditions that fall to the lot of the physician to handle, there is none that equals that condition of advanced cardiarenal disease, with high blood pressure, auricular fibrillation, and heart block, where the Ceyne-Stokes respiration has appeared and is persistent.

The blood pressure is low or high in serious heart disease, in proportion to myocardial change or kidney complication. In rapid degeneration of the cardiac muscle the systolic pressure may drop a hundred millimeters in a few months. It is a grave mistake to reduce the systolic with nitrites or other depressants; for the diastolic pressure tension is not correspondingly reduced and the heart is depressed. Some cases attended by high blood pressure are greatly relieved by free cartharsis with salts. A full dose of cream of tartar at bed time is useful, and some patients are greatly benefited by a mighty blue mass pill for a long period. As a general treatment for serious heart disease, where respiratory difficulties occur, rest in bed is important, but in some cases where cyanosis is absent the patients do better with a little exercise gradually increased.—*Texas State Journal of Medicine.*

Thinness and Life Assurance.—The presence or absence of thinness is of definite importance to the medical officer of life insurance companies, since one of the factors on which estimation of risk is based is the constitution of the assured, of which thinness is one type. Some companies exact an extra premium on account of thinness on those whose weight is 20 per cent below the standard, others take into account the relation between the height and the chest measurement; while others, again, rely on a "constitutional coefficient" calculated from a comparison of height, thoracic circumference, and weight. Dr. Romanelli, in *Il Policlinico* (February, 1916), draws attention to the great practical importance of the "bi-acromial diameter" in calculations of this kind. This diameter is measured from the extremity of one acromion to the other, passing in front of the thorax, and has the merit of having two fixed and easily found bony points and of being a fairly accurate estimate of the development of the body in breadth and of the thoracic development. Dr. Romanelli places the lives to be insured into two classes in this respect; those whose weight is 15 to 20 per cent. below the standard and those whose weight is over 20 per cent. below. He endorses the opinion of Dr. Haviland Hall that thin lives not exceeding 15 per cent. of underweight should not be refused. but that those who pass this limit should only be accepted after a rigorous examination, and that if there is tuberculosis in the family a life below 30 years should be rejected.—*The Lancet.*

Book Reviews.

THE PROCEEDINGS OF THE CHARAKA CLUB. Volume IV. New York. William Wood & Company. 1916.

WHILE the study of the history of medicine cannot, perhaps, be considered an essential part of medical education, it certainly is the most desirable of its embellishments. The Charaka Club has long held an enviable position because of its successful work in the collection and dissemination of information on medico-historical subjects and literary and artistic matters bearing on medicine, and the appearance of the fourth volume of its proceedings is therefore a welcome occasion. The papers presented cover a wide range of topics of much interest. A botanical view of the Shakespeare-Bacon controversy, the University of Alexandria, the medical publications of the Elzevirs, medical data from old church history, Saints Cosmo and Damian, and other titles of fascinating interest head articles that well repay attention. This volume contains twelve articles in all by eight contributors, namely, Drs. Gerster, Walton, Collins, Mumford, Dana, Bailey, Pilcher, and Streeter. The Charaka Club deserves the thanks of the profession for its efforts to keep alive in us the history of our medical forefathers and the memories upon which our modern practice is founded.

ALCOHOL—ITS INFLUENCE ON MIND AND BODY. By EDWIN F. BOWERS, M.D. Price, $1.25 net. New York: Edward J. Clode, 1916.

THIS book is intended for popular consumption rather than as a contribution to medical literature and is a palatable presentation of the case against alcohol. Statistical studies are diluted and disguised until they are made to appear entertaining reading. Examples of the writer's facility in coining trenchant phrases are such chapter headings as "The Emperor of Drugs" and "Beer, the Brutalizer." The greater part of the evidence against alcohol is furnished by Kraepelin's well-known studies, which are, of course, familiar to the profession by this time. The crux of the alcohol problem, that is, the fact that alcoholism is a symptom, is not mentioned by Dr. Bowers, wisely enough. He likewise does not allude to the studies of Haycraft, who found an increase in the admissions to poorhouses and insane asylums in States where prohibition had been in force several years. A fact of this kind is difficult to present to a lay audience on account of the necessity for explaining away the obvious inferences. The consensus of opinion of students of inebriety is that, even apart from his alcohol, the inebriate is not normal, but here again an investigation of this circumstance would lead into rather deep waters, so it is not attempted in the present volume. Dr. Bowers' book is, however, interesting and should find a large circle of readers.

A TEXTBOOK OF FRACTURES AND DISLOCATIONS. With Special Reference to Their Pathology, Diagnosis, and Treatment. By KELLOGG SPEED, S.B., M.D., F.A.C.S. Associate in Surgery, Northwestern University Medical School; Associate Surgeon Mercy Hospital; Attending Surgeon Cook County and Provident Hospitals, Chicago, Ill. Octavo of 888 pages. Illustrated with 656 engravings. Price, $6 net. Philadelphia and New York: Lea & Febiger, 1916.

THIS is a very satisfying book, among other reasons because the author, as he states in the preface, has himself performed the labor of writing the text; there is very little of the flavor of compilation and relatively few pages that do not bear the unmistakable imprint of the author's personality. There is also everywhere evidence of the author's thorough study of the literature as well as of his comprehensive grasp of the subject on the basis of actual personal experience. The author very properly insists upon the value and necessity of a thorough knowledge of the histology and pathology of bone, at least in so far as fractures are concerned, and upon this the development of the subject is based.

There are no sweeping criticisms that can be made, although, in common with most first editions, there are occasional errors of omission and of commission. One rather common fault in first editions is incompleteness of the index and upon looking up a number of subjects at random we find that this book furnishes no exception in that regard. There are relatively few typographical errors, but proper names are occasionally misspelled. Hey Groves, for instance, is sometimes spelled correctly, sometimes Hey Grooves. In discussing the Rainey wooden splint the method of application is not adequately described and the photographic representation of a patient in bed with the Rainey splint applied throws no light upon the matter. As to the author's remarks on the operative treatment of fractures, we must say that the advantages of the inlay graft do not seem to be appreciated, and we trust that this section will be found much revised when a second edition appears.

On page 69 he says: "Volkmann's ischemic contraction is the term applied to a type of contraction of the muscles and the changes in the soft parts distal to the point of fracture." Since in many instances this condition affects the muscles of the forearm in cases of Colles' fracture, it is evident that the lesion need not necessarily be *distal* to the point of fracture.

In spite of these and a few other matters calling for criticism the fact remains that Speed has written not only a good book but one of the best devoted to this subject. The subject matter is well presented, practically all methods of treatment in general use are well described, illustrations are abundant and generally to the point, and the book is equally well fitted for the use of student, general practitioner, and surgical specialist.

OPHTHALMOLOGIE DU MÉDICIN PRACTICIEN. Avec 347 Figures Dans le Texte et Une Planche Hors Texte en Couleurs. Price, 12 fr. Paris: Masson et Cie, 1916.

THIS work appears in a volume of 480 pages. It is well illustrated by many figures in the text and one colored plate. The book is for the use of the general practitioner particularly. After defining the desired position of the general practitioner regarding ophthalmology as to his knowledge of the subject and his relation to the ophthalmic patient, the direct consideration of the subject is entered into. The necessary instruments to be procured by the general practitioner are designated, methods of examination with systematic chart. Remedies employed and their application. A chapter is devoted to injuries to the eye and its adnexa. The diseases of the eye are then systematically considered in a brief and concise manner. A chapter is devoted to the consideration of eye affections complicating general disease. A short chapter on the hygiene of the eye and prophylaxis follows. The work is well adapted to serve the purpose for which it was written, namely, for the use of the general practitioner.

PROGRESSIVE MEDICINE. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by HOBART AMORY HARE, M.D. Professor of Therapeutics, Materia Medica, and Diagnosis in the Jefferson Medical College, Philadelphia. Assisted by LEIGHTON F. APPLEMAN, M.D. Instructor in Therapeutics, Jefferson Medical College, Philadelphia. Price, $6 per annum. Philadelphia and New York: Lea & Febiger, June 1, 1916.

THE current number of Progressive Medicine contains the following contributions: "Hernia," by W. B. Coley; "Surgery of the Abdomen, Exclusive of Hernia," by J. C. A. Gerster; "Gynecology," by J. G. Clark; "Diseases of the Blood, Diathetic and Metabolic Diseases, Diseases of the Tryroid Gland, Spleen, Nutrition, and the Lymphatic System," by A. Stengel, and "Ophthalmology," by E. Jackson. We have so frequently drawn attention to this admirable publication that there is no need to enlarge on its merits. But it is a pity that the present number should be marred by such a wretched index. Under the heading "Uterus, Cancer of," not one of the references is correct; "Cancer" is similarly mishandled, and many other entries give the impression that the index does not belong to the present volume.

THE INVOLUNTARY NERVOUS SYSTEM. By WALTER HOLBROOK GASKELL, M.A., M.D., F.R.S. Author of "The Origin of Vertebrates," etc. With colored figures. Price, $1.80. New York: Longmans, Green and Co., 1916.

THIS volume by the late Dr. Gaskell is one of a series of monographs on physiological subjects which is being edited by Professor Starling. Unlike several recently issued works on the sympathetic and autonomous nerve systems the present volume deals principally with the innervation of non-striated muscle in the entire vertebrate kingdom, beginning with the reptiles. Having purely an experimental foundation, the work does not include mankind. Doubtless it represents an outgrowth of his book on the origin of the vertebrates.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held April 20, 1916.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

THE Council of the Academy submitted the following resolutions which were unanimously passed:

Resolved, That the New York Academy of Medicine approves of the establishment of dental colleges in connection with universities having medical departments.

Resolved, That the New York Academy of Medicine views with regret the inadequate provision made for the medical service in the bills now before Congress for increasing the Army of the United States, which gives less than five medical officers to one thousand combatants, whereas experience in the present war in Europe indicates that ten medical officers to one thousand combatants are necessary under conditions of actual warfare. The ratio in the Army of the United States in peace time should not be less than seven medical officers to one thousand combatants, to be increased to ten per thousand in war time.

The subject of the evening was the "Discussion of Some Recent Developments in Our Knowledge of Food Values, and Their Bearing upon the Causation of Disease and upon Its Management."

Vitamines a New Factor in Nutrition.—Dr. CASIMIR FUNK read this paper in which he said that recently sufficient evidence had accumulated to warrant the statement that besides the ordinary food constituents, such as proteins, fats, carbohydrates, lipoids, and inorganic salts, to the presence of which with the exception of salts the caloric value of our food was due, a number of substances could be found in very small quantities which were as indispensable to life as the former constituents. These substances were elaborated in both the lower and higher plants, but could not be synthetised by the animal organism, and this was one of the reasons why animal life depended upon plants. These products were present in all our foods, in all our organs, and in all vital parts of the plant without a single exception. Their presence had been revealed to us by the modern technic of cooking and by the refinement of food due to the introduction of machinery for the industrial preparation of foodstuffs on a large scale. After referring to the etiology of beriberi as due to polished rice, the writer stated that another origin of the same disease was in other refined foods like sago, tapioca, white bread, especially when baked with baking powder, consumed in disproportionately large quantities, or if our usual food was subjected to prolonged boiling as sometimes happened when food was prepared in very large quantities as in the army and in prisons and in other institutions. The insufficiency of these substances had also been noted in cases of mental disturbance in which a fancy was taken to one particular food. Without going into the detail of the extraction and preparation of these substances, it might be stated that they were dealing here with products showing a good deal of instability under ordinary laboratory conditions. This point might be best illustrated by referring to the time it took to isolate adrenalin from the suprarenal glands, which was partially due to the fact that this base was present in small quantities, and that an insufficient amount of starting material was taken for fractionation, and also to the fact that adrenalin was easily oxydizable in alkaline solution. When precautions were taken to eliminate these factors the isolation of adrenalin was successfully accomplished. It then took a number of years to inform them of its chemical properties and constitution, and then further time for its successful synthesis. It would take even longer to ascertain the constitution and composition of the vitamines, since as yet the difficulties of the first stage had not been overcome, and this had liminted the valve of investigations with reference to the second stage to some extent. However, sufficient evidence had been accumulated to warrant the designation of these substances by the term "vitamines" and the diseases which arose from their lack or insufficiency as deficiency diseases or "avitaminoses." Dr. Funk expressed surprise that the introduction of this term had aroused so much animosity, since it was quite customary to give a name to substance the presence of which was merely assumed before its actual isolation, and such terms were usually accepted until further evidence disputed their presence. The evidence for the existence of the vitamines was many times stronger than in most cases where similar terms had been introduced. The chemical evidence for the existence of these substances could be seen from the methods of their detection. After calling attention to the difficulty of fractionating and identifying substances obtained in such small quantities, the writer said that the vitamines were sometimes stable at higher temperatures in the presence of acids and could be thrown down by phosphotungstic acid or analogous reagents which were so largely used for the isolation of nitrogenous substances, and afterward could be fractionated by means of mercuric chloride and silver nitrate and baryta. From this final precipitate a crystalline fraction could be obtained which in relatively small quantities cured beriberi in pigeons. This precipitation was specific for vitamines, and they were not merely carried down as was supposed by some investigators. Other precipitating agents which also yielded heavy precipitates did not carry down the vitamines. While this work had been confirmed by many observers it must be admitted that further chemical evidence was desirable, especially as regards the mode of combination of the vitamines in the tissues. With reference to the action of the vitamines nothing very definite was known except that they bore a certain relationship to the carbohydrate metabolism. Dr. Funk had found that feeding animals on a food composed largely of carbohydrates brought on an earlier appearance of the symptoms of deficiency diseases. For instance, if a pigeon was fed on polished rice it was possible to estimate approximately when the symptoms of beriberi would appear when a given quantity of rice was metabolized. The writer had confirmed this with an artificial diet composed of variable amounts of carbohydrates, and it was also found that the blood sugar content in avian beriberi was greatly increased. This fact had a practical bearing in infant feeding. It must be borne in mind that a certain amount of vitamine could only take care of a limited amount of carbohydrates, and when starch was increased in the diet the amount of vitamine-containing foodstuffs must be increased in proportion. A second fact which had been established in connection with the metabolism in deficiency diseases was that in the absence of vitamine we obtain not only a negative nitrogen balance, but the whole metabolism goes wrong. This was particularly noticed in the negative balance of inorganic constituents, like calcium, phosphorus, and sulphur. Schaumann had recently shown that the addition of vitamine put the whole metabolism again on a normal basis, and this fact was of special importance for the understanding of certain conditions like rickets in children. It was found further that vitamine when properly prepared and added in sufficient amount to polished rice would make the latter diet complete. The writer had shown in addition that no animal was yet found able to live more than a short time on a vitamine-free food, and that an artificial diet composed of casein, starch, fat, sugar, and all the necessary salts would produce a deficiency disease of some kind, according to the animal chosen, provided sufficient care was taken to purify the ingredients. To this diet all known lipoids, cholesterol, various proteins, and all sorts of salts could be added, but nothing could save the animal or man from certain death unless vitamine was added. Dr. Funk then proceeded to discuss certain points in reference to the relation of the vitamines to the deficiency diseases, calling special attention to the experiments of Morgen and Beger, who found that rabbits fed on oats, a diet supposed to produce scurvy in them, could remain in good health when sodium bicarbonate was added. They considered therefore that the condition produced was an acidosis, and certain experiments which the author had performed seemed to confirm this statement to some extent. However, the same experiments in guinea pigs produced a condition that was possibly scurvy, but certainly not acidosis. As to pellagra, when he first expressed the opinion that this was a deficiency disease he had met with great opposition, but now the etiology of this disease as a deficiency disease seemed to be clearly established. It seemed possible that pellagra was nothing but a chronic scurvy, and that we knew as scurvy was the acute form of the same disease. The vitamine theory as to the etiology of rickets was at present a mere working hypothesis. The results of animal experiments suggested that they were dealing with a deficiency disease due to a deficiency of vitamine which was not essential for life, or to a partial deficiency of the ordinary vitamine. The opinion of certain workers that rickets had its cause in a lack of calcium was very largely due to a misinterpretation of their experiments. From the point of view of the vitamine theory there was no objection to congenital rickets when the mother's diet

was deficient, and there was no objection to rickets in breast-fed babies, in adults as osteomalacia, and in old age perhaps under another name. The writer next considered the problem of growth, worked up in conjunction with Dr. A. B. McCollum, and referred to the work of McCollum, Osborne, and Mendel who had tried to demonstrate that butter had a very decided effect on the growth of rats, and had stated that butter-fat did not contain nitrogen. He was now able to demonstrate that rats could grow very well without butter when a sufficient amount of vitamine was added to the diet of the rats, and hence he was utterly unable to confirm the results of McCollum. When working with yeast it had been noticed that rats on dried yeast grew well, but had shown slight symptoms of scurvy, which, however, disappeared when autolyzed yeast was used. This possibly showed that rats required for their wellbeing both the beriberi and scurvy vitamines. Successful growth was also obtained by using phosphotungstate precipitate decomposed from autolyzed yeast, while the filtrate had no action whatever. The fraction used was entirely free from material which could not be extracted with lipoidal solvents, and this alone proved that the water-soluble portion of yeast was the only one responsible for the growth of rats in direct contradistinction with the recent statement of McCollum. Experiments which the writer had conducted in association with Dr. Morris Stark showed also that McCollum's assumption that casein lost, when heated with alcohol, its nutritive value was baseless. At present they were not able to say whether autoclaved casein heated at higher temperature had a full nutritive value or not, and it was possible that the latter casein would require an addition of tryptophan and cystine. Dr. Funk and Dr. McCollum had found, however, that by means of a suitable diet they could make rats grow twice as fast as on a diet regarded hitherto as normal. At the same time they were able to stunt animals on a diet that might be designated as normal. This result had been obtained in chickens fed on unpolished rice, and still better by feeding unpolished rice and codliver oil. The same could be accomplished with rats on a diet of oats. These results could be applied to the growth of children. It was of interest in this connection to know that they had been able to show that tumors in rats and chickens did not grow so extensively on such a diet as on a rich diet, and also that the tumor had a greater affinity to these substances than somatic cells. While cancer had nothing in common with the deficiency disease and was if anything a disease entirely opposed to avitaminoses, it seems extremely probable that cancer was not of infectious origin, but was due to a chemical cause, and the study of diet in cancer will be in the future one of the most important lines of research.

Group Similarities of the Deficiency Diseases, as Illustrated by the Clinical and Experimental Study of Infantile Scurvy.—Dr. ALFRED F. HESS presented this communication, in which he first called attention to the fact that infantile scurvy almost never developed among breast fed babies, but was encountered among those who were fed on cow's milk, and more especially those who received in addition some of the proprietary foods which were so commonly resorted to in the preparation of milk formulae. There had been a difference of opinion as to whether the use of pasteurized milk could induce the scorbutic condition. The commission on Milk Standards, in its report of 1912, stated that pasteurization did not destroy the chemical constituents of milk and that it was not altered by exposure to heat under 145° F. Dr. Hess determined to test the validity of this statement and, accordingly, among a certain number of inmates of an infants' home, where all babies were fed on Grade A pasteurized milk which had been heated to 145° F. for thirty minutes, the use of orange juice was discontinued. No other change was instituted. The results of this apparently minor dietary change might be summarized by the statement that almost all the infants who did not receive orange juice developed a more or less marked form of scurvy, whereas those who continued to receive orange juice remained entirely free from this disorder. Most of these infants had been in the institution from birth, so that their condition, both before and subsequent to the change, could be thoroughly observed. The results of this investigation, which was published some two years ago, were questioned by some who were loathe to believve that pasteurized milk could in any way lead to scurvy, and hence the investigation was extended somewhat in the subsequent year. The results were the same, so that the writer felt safe in saying that a diet of pasteurized milk led to the production of scurvy in infants unless some antiscorbutic food was also given. This scurvy was not as a rule of the florid type met with in infants fed for months upon proprietary food, but might be described as latent or rudimentary scurvy. There was a gradually increasing pallor, a failure to gain in weight, the development of some petechial hemorrhages, and in more marked instances, the subperiosteal hemorrhages. It would seem probable that this insidious type of the disorder was far more common than was generally recognized by physicians and that there were many infants suffering from slight nutritional disturbances which might be ascribed to this cause. When the pasteurized milk was replaced by raw milk the scorbutic condition improved, although it might be added that raw cow's milk was by no means comparable to orange juice as an antiscorbutic. It was not to be inferred from these conclusions that the use of pasteurized milk was fraught with danger, but merely that it was an incomplete diet for babies and must be given with antiscorbutic food. There were also secondary factors contributing to the development of scurvy, such as the individual variation depending upon hereditary characteristics, that was, upon the amount of antiscorbutic material which the infant brought with it when it came into the world. Secondary food factors also seemed to play a part, malt preparations seemingly predisposing to scurvy and it also seemed probable that there was an intimate relation between the development of scurvy and the amount of carbohydrate in the dietary. Infantile scurvy differed clinically from the other deficiency diseases mainly in the fact that it was characterized by the production of hemorrhage in various parts of the body, which a study of the pathogenesis showed to be due not to alterations in the blood itself, but to alterations in the blood vessels which were probably to be regarded merely as a part of the general cellular and tissue changes which occurred in this disorder. In considering the clinical relationship between beriberi and infantile scurvy he expressed the opinion that the current clinical viewpoint which regarded infantile scurvy almost as one of the hemorrhagic diseases and the current pathological viewpoint which centered its attention on the changes in bone structure were far too limited in their scope. Signs of involvement of the nervous system were the characteristic manifestations of beriberi and a study of the cases which came under his observation showed that infantile scurvy was not entirely free from nervous signs. The knee-jerks were frequently found exaggeratd, and in some instances there was slight involvement of the optic discs and sensitiveness of the cutaneous nerves seemed to be present. These symptoms disappeared when the nutrition became normal again. Again dilatation of the right heart had frequently been described in beriberi, and this was noticed by Andrews in infants who were nursed by women with this disease and had been found to occur likewise in infantile scurvy, as had been demonstrated by numerous Roentgen ray examinations. Edema was also a common symptom of the two conditions. Further evidence was also available showing the interweaving in the symptomatology of these two diseases. There was also evidence demonstrating essential differences in the vitamines controlling the development of these allied disorders. The sovereign cure of scurvy was orange juice, which was efficacious even when boiled for ten minutes; potato, one of the best antiscorbutics for adults, might be employed in infant feeding where orange juice could not be readily obtained. For this purpose milk could be diluted with potato water, one tablespoonful of mashed potato to one pint of water, instead of the usual cereal decoctions. In connection with this work observations were carried out as to the effect of infantile scurvy on growth, the study embracing an interval of one year or more. Three periods might be distinguished in this investigation, a preliminary period of about three months, during which the infants were weighed daily and measured every two weeks; a second period embracing about four mouths, during which the infants received a liberal diet of pasteurized milk and cereal, which differed from the previous diet only in the fact that no orange juice was given; and an after period, lasting about six months, which dated from the time when orange juice or other antiscorbutic was once more added to the food. During the period when the antiscorbutic was discontinued particular attention was given to furnishing a sufficient quantity of food, and more cereal was given or the strength of the milk mixture was increased. It was found that although the infants continued to gain in most instances for a few

weeks following the discontinuance of the orange juice, they soon reached a stationary plane and for months were unable to rise above this level, but increased in weight promptly when the antiscorbutic food was again added to their diet. This gain took place in some definite cases in spite of the fact that the infants did not take an increased amount of food, showing that the orange juice either brought about a more perfect metabolism, or what was more probable, contained substances capable of stimulating the growth promoting function. It was very probable that infants frequently ceased to gain at about eight months of age, during the third quarter of the first year of life, for the want of this essential addition to their food, and failed to progress until mixed feeding was begun some months later. At present the rule might be said to be to add fruit juices to the dietary at about the sixth month, probably because scurvy seldom developed during the first six months of life. At this time incidence was due to the fact that the infant had been protected for the first few months of life by the supply of antiscorbutic material which it had inherited from the mother, and that there must have been a constant negative balance of these essential substances dating from the earliest beginning of artificial feeding. It would therefore seem that a corrective dietary, that was an antiscorbutic should be given as soon as possible. There was no reason why an infant should not receive orange juice when it was a month old, and there were strong arguments in favor of such a procedure. A number of the infants were not only weighed, but were frequently measured. This group included about twenty, one-half of which number received orange juice, whereas the others did not. As a result it was found that scurvy not only had a direct effect on the weight, but also upon the growth in length, and that orange juice contained properties corrective in both respects. This fact was of greater biologic interest than failure to gain in weight, for as had been shown by Freund and Variot growth in length was a physiological impulse to which the human species clung with great tenacity, and which was rarely affected even when other functions were held in abeyance. Although it was true that infantile scurvy and lack of growth went hand in hand, such was not always the case, as one of the infants in this series gained steadily in weight in spite of the fact that it was developing scurvy. Instances such as this showed that lack of growth did not play an essential part in the constitution of this disorder. A deficiency of scurvy vitamine was one cause of stunting; lack of sufficient or adequate food another, and no doubt there were other factors. Whether or not growth occurred and to what extent, depended upon the resultant stimulation brought about by these various impulses.

Dr. L. Emmett Holt said that his remarks were made from the standpoint of the clinician and were based only on observations made at the bedside. His interest in this question was not whether the substances under discussion were vitamines or amino acids, or what particular name should be given to the substances the lack of which produced deficiency diseases, but rather as to the clinical manifestations of these conditions. He believed that scurvy was much more frequently seen since the general introduction in this city of pasteurized milk. To his mind the evidence was conclusive that the connection was one of cause and effect. Boards of health were properly impressed by the part that milk had played in the transmission of septic sore throat and typhoid fever, but it was unfortunate that they should have neglected to warn the public that pasteurized milk might produce scurvy. It had been claimed that if scurvy occurred in an infant on pasteurized milk it was always the fault of the milk formula used and could not be ascribed to the heating. This was a difficult position to maintain. While it was certainly true that the occurrence of scurvy showed that the food was not proper, this was far from proving that other proportions of the fat, carbohydrate, and protein used would have given a different result. Dr. Holt did not think that the addition of cereals to milk as commonly employed in infant feeding gave any protection against scurvy if milk was heated; but rather that additions of considerable amounts of carbohydrates, particularly in the form of starchy foods and maltose mixtures, increased the liability to scurvy in heated milk. He did not wish to be understood as voicing an indictment of pasteurized milk, whose great advantages he fully appreciated, but simply to call attention to the disadvantages which must be considered as well. The use of pasteurized or sterilized milk over long periods was always attended by the risk of producing scurvy unless some antiscorbutic was added.

Dr. Warren Coleman said that one of the most interesting phases of the vitamine problem for the clinician was the question whether the diets used in the treatment of any of the commoner diseases with which we had to deal were deficient in these important substances. There was no common disease of adults, occurring in this latitude, which was recognized to be due to the lack or insufficiency of vitamines. Yet it was not impossible that ill-defined types of disorders now thought to be disturbances of function, or some of the symptoms of well-established diseases, might have this origin. He was the more ready to credit this possibility because of his experience with typhoid fever. For example, he believed that the very course of the disease had been altered by giving patients all of the food they required instead of only a part of it. He no longer considered diarrhea a symptom of typhoid fever, except perhaps in the prodromal stage, but thought that it was the result of improper diet and it ceased when the diet was properly arranged. Delirium and the typhoid state were not essential symptoms of the disease. Delirium might occur, but when it occurred it was due either merely to the fact that the temperature was elevated beyond a certain height for a particular individual, or to the elevated temperature plus starvation. If in so well known a disease as typhoid fever such prominent symptoms could have been considered essential symptoms of the disease, it was quite possible that some of the symptoms of other diseases, or at least some disorders not now understood, might be found to be due to diets deficient in vitamines. Attention should be directed to this point, however, that the so-called bland diets of the text-books ordinarily consisted of foods with a high vitamine content such as milk, eggs, and meat extracts, unless they had been heated too high.

Dr. Morris Stark said that in the course of the evening's discussion in referring to the deficiency diseases, not much stress had been laid on the possibility of rachitis being considered as a deficiency disease, as had been suggested by Dr. Funk and others some time ago. There was enough evidence in the literature of rachitis to say nothing of as yet unpublished work now going on, to tempt one to assume that rachitis was a metabolic deficiency, at least until it could be proven or disproven to be such by further work along the lines of metabolism experiments upon the human infant. If such experiments could definitely show, as he had not the slightest doubt they would show, a change in the mineral metabolism as a result of the administration of substances designated by Dr. Funk as vitamines, substances in themselves free from these salts in any appreciable amounts, in addition to the diet which produced the deficiency disease, a diet in itself not lacking these salts in necessary amount for the needs of the body, but lacking in vitamines, their point was proven and the mystery surrounding rickets solved. The literature already published by Dr. Funk showed ample evidence in justification of the term vitamine as applied to these substances. That this group of substances was just as necessary to life as those amino-acids which had proven themselves also necessary for the normal existence of the organism, would readily demonstrate itself to anyone making as careful chemical and physiological tests as Dr. Funk and his collaborators had made, tests which, though questioned, had never been disproven in publications by anyone so far as he knew. As to whether the boiling of milk diminished its nutritive value, at least the nutritive value of the casein, it seemed so far as their experiments had shown that boiling casein did not destroy its food value, as supposed by McCollum, but it undoubtedly did destroy the vitamines, as shown by the cessation of the growth of rats fed upon it and their return to normal growth when a vitamine containing substance, such as yeast, was added to the food. McCollum's findings as to the necessity of butter for growth seemed to be controverted by Dr. Funk's experiments referred to in his paper. From many authoritative sources they were led to believe that yeast contained a large proportion of vitamine, and accordingly, observations upon the effect of the administration of autolyzed yeast to rachitic children were now being conducted by the speaker at one of the outpatient departments with the possible finding that a distinct increase of appetite was the result. Rachitis in breast fed babies and also its occurrence very early in other infants artificially fed was being further in-

vestigated by a careful study of the diet of the mothers during pregnancy and lactation. However, they were still far from saying the final word upon this subject and upon the relation of vitamines to rachitis.

Dr. Abraham Jacobi said it was an undisputed fact that scurvy was very frequent nowadays when so many babies were being artificially fed. Forty or fifty years ago it was very rare. Scurvy was apparently produced by over-sterilization of the milk. Pasteurized milk would not cure or even prevent scurvy, but it did not by itself cause it. Pasteurized milk with a cereal would do better and would sometimes prevent or cure scurvy, but not every over-refined cereal would do this, only cereal in the raw state. If there was no husk left on it there was no advantage to the baby. Raw barley or oatmeal were the most efficacious materials to add to the milk. A second point to be noted was that breast fed babies rarely had scurvy and for the reason that the milk from day to day, from morning to evening, was never the same; it had the advantage of being changed frequently. As long as a baby was fed on uniformly the same food, eventually he would get scurvy.

Stated Meeting, Held May 18, 1916.

The First Vice-President, Dr. Edward D. Fisher, in the Chair.

This meeting was held in association with the American Society for the Control of Cancer.

The Interests of the Community in the Problem of Cancer.—Louis I. Dublin, Ph.D., statistician of the Metropolitan Life Insurance Company, presented this communication. Contrasting cancer with tuberculosis, he stated that the average age at death from tuberculosis was about 37 years; from cancer it was about 20 years later. Tuberculosis primarily affected the economic interests of the community. The decedent was usually at the highest point of his efficiency; his productive period was still largely in the future; his children were either still young or yet unborn. In cancer, on the other hand, the productive period was for the most part in the past; the children had been born and the family unit was only slightly disturbed economically by the death, since in the majority of cases the offspring had reached the age of self support and independence. It was, therefore, the emotional interest that was uppermost. To-day cancer was responsible for one death out of every 14 among men and one death out of every nine among women after the age of 50 years. The present interest of the public in cancer was further accelerated by the mystery that surrounded the disease and which had thus far baffled all efforts of the physician and the scientist. Additional interest resulted from the disquieting fact that the cancer rate might be increasing. The chief sources of information indicated an increase. This held true not only for the registration area of the United States, and for those of our states whose records were most reliable, but also for the United Kingdom, for Switzerland, for Germany, and, indeed, generally throughout the civilized world. Equally good authorities were divided as whether this increase was real or only apparent. The speaker was of the opinion that there might very well be an increase. The figures, however, seemed too striking to be true. In the ten year period from 1901 to 1910, there was an increase of 30 per cent. in the male cancer rate and of 22 per cent. in the female cancer rate, at all ages, beginning with 25 years, in the states included in the registration area in 1900. At certain periods this increase was very considerable, as much as 40 per cent. The unreliability of these figures was at once apparent when we thought of cancer as a disease of long standing in our civilization. By projecting such increases in the rates forward or backward a few generations in time one was led at once to an absurdity; for if cancers are capable of increasing at such a pace it would either have been a negligible disease in the past or would seriously threaten the existence of the race in the near future. The marked improvement in registration must be taken into consideration and the greater certainty in the diagnosis of cancer by physicians. We should have to wait at least ten years under present conditions of registration in this country to know definitely what had happened. Whether cancer was on the increase or not was secondary to the fact that the rate at present was extremely high, and conditions to-day a real menace. In order to demonstrate the extent of the problem the essayist presented certain data which he stated were valuable because of their intrinsic value. They had also the merit of being based on a large exposure, there being represented over ten million persons, both white and colored, men, women, and children, of all ages, above one year. From this table it was shown that the rate at all ages was 69.7 per 100,000 exposed. This table showed, among many interesting details, that the cancer rate was much higher among females than among males; that the cancer rate began to be significant only with the decade 25 to 34; that thereafter the rate increased very rapidly, until the maximum was reached at the age of 75 and over. This was true for both sexes and for both white and colored persons. The rates were lower for the colored than for the whites, and this applied more to males than to females. It had often been said that cancer was a disease of the well-to-do; the figures showed, if anything, that the industrial classes enjoyed no advantage. It seemed that no large groups in the community enjoyed any special immunity. The Jews had been singled out as enjoying a special or partial immunity. The rate for Jews was sometimes higher than for the native born Americans of the corresponding age periods. Another table illustrated the relative importance of the several forms of cancer which occurred among males and females of the two races. This table showed that among white males about one-half of the cancers affected the stomach or liver; about 20 per cent. more related to other parts of the digestive system, namely, the buccal cavity, the peritoneum, the intestines, or the rectum. Together over 70 per cent. of the cancers among males were so accounted for. Among females cancer of the genital organs and cancer of the breast were very prominent. The former was responsible for 43.1 per cent. of all the cancer deaths occurring among the colored; 15.9 per cent. in addition were due to breast cancers. Cancers of the skin were much more numerous among males than among females; the rate was extremely low for colored persons, being virtually negligible among colored females. In general, there was clearly a larger proportion of external and surgically accessible cases among females than among males. Hospital statistics showed that the cancers which were responsible for the large part of the female mortality, those of the genital organs and the breast, were most susceptible to treatment. Therefore, a large reduction in the female cancer mortality might be expected from organized efforts to bring cases to early treatment. A third table showed the average ages at death of the persons who had died of cancer of the various forms. The average age of females at death was about two and one-half years lower than that of males: 54.8 years as against 57.2 years. The highest average age was 63.7 years for cancer of the skin among females; the lowest 51.1 years for cancer of the female genital organs. A discussion of the average age at death was important because it was an indication of the loss to the community that was occasioned by cancer deaths. At the present time a conservative estimate placed the total number of cancer deaths in the United States at 80,000 a year. This meant an aggregate loss to the community of 1,200,000 years of life, basing the life expectation as accepted at the present time in New York City. Not considering the monetary value of this loss, it would be a gain to civilization of no mean value to extend to persons of middle life and early old age a few additional years of peaceful enjoyment. That the happiness of thousands of families would be preserved and that thousands of individuals would be spared unbearable pain meant more to the community than could be estimated in dollars and cents. To accomplish this end two lines of effort were clearly indicated. The first was to reduce at the best means at our disposal the suffering and premature death of cancer patients. At the present time the greatest promise of success was held out by the surgeon. The statistics indicated that with early diagnosis followed by immediate operation the average duration of life of cancer patients could be appreciably prolonged. If an average of five years could be added to these lives, this would be equivalent to a reduction of more than one-third the total loss. This was clearly the community's immediate program. The second line of effort lay in investigating into the basic facts of cancer, the etiology of the disease, its method of dissemination, the problem of inheritance, and finally the measures of relief. This was the field of the pathologist and the surgeon. A contribution to this

effort was being made by the life insurance companies, which promised to cast valuable light on the entire problem. They had made all the necessary preparations to carry on a special study of the life insurance returns from two forms of cancer which were readily diagnosed—cancer of the buccal cavity and cancer of the breast. Forms had been drawn up for this purpose, which it was planned to send to the physician who signed the death certificate on the claim papers and to ask him for more information in reference to the case. In closing the essayist expressed the hope that these forms would receive the careful and enthusiastic attention of physicians.

Our Present Knowledge of the Nature of Cancer.—Dr. FRANCIS C. WOOD made this contribution. He stated that the interest of investigators in cancer was almost wholly due to the fact that they wanted to cure it, interest in the discovery of the cause being largely scientific and academic. It might be quite possible to discover a cure for cancer before the cause was known, as was the case with malaria, anemia, and syphilis. Unfortunately, at the present time, the only cure known was complete and early removal of the tumor by surgical operation before it had spread throughout the body. Before they could intelligently devise or even attempt to devise a cure, they must know a great deal about the nature of cancer: What it was, how it grew. Why it did not disappear of itself. Put in its simplest terms, a cancer might be described as a wild growth of some tissue of the body. It was extremely important to remember that these cancer cells did not come from outside the body, nor were they due to bacteria or to any parasite; but they were the cells of one's own body. Hence the difficulty of finding a cure, because to destroy these cells meant to destroy also the cells of the tissue or organ of the body from which they grew. The diagnosis of internal cancers was still the great difficulty in their treatment, for almost any internal cancer could be removed, except one which was in the interior of an important single organ, such as the brain or liver. Until some medicinal cure was discovered, it was important to develop every possible means of diagnosis. This was the portion of the cancer problem that belonged to the practitioner of medicine and surgery. The question of discovering what cancer was and the details of the way in which it grew belonged, on the other hand, to the scientific workers in laboratories. This investigation must of necessity be confined to animals, and fortunately for the human race the antivivisectionists had not yet rendered it impossible for us to study the disease in animals. Most animals suffered from cancer in one form or another, and these cancers could be transplanted easily and painlessly by the simple process of injecting hypodermically a small portion of the fresh tumor tissue. This cancer tissue when placed in an animal of the same species would often grow much as the original cancer did, but unfortunately it did not grow in exactly the same way because it was implanted in a new healthy strong animal. This animal frequently resisted the introduction of the cancer and either refused to permit it to grow at all or offered such resistance to the growth that after a few months the tumor disappeared. This absorption greatly complicated the study of cancer, because in trying out a cure they had to be very careful that the disappearance of the tumor was not due to other causes than the remedy administered. Only such tumors as went on and grew steadily until the death of the host resulted should be used in testing out a supposed cancer cure. The tumors which spontaneously disappeared often left the animal immunized against a second implantation and this fact had enabled them to study the conditions which led to the refusal of the animal's tissues to adapt themselves to the new growth. The study of such grafts led to the interesting conclusion that, if the tumor was to take, the animal tissues quickly provided the small mass of cells injected with suitable blood vessels to nourish it, thus showing that the tumor cells did not cause any reactions against themselves, as did ordinary cells such as the cells from the surface of the skin. If these latter cells were injected they would be promptly destroyed by the active cells of the body. The cancer cell was the one then which had lost this power of inciting resistance to itself and the animal's tissues did not recognize the existence of a dangerous invader until it was too late. On the other hand, if the animal was resistant to a particular tumor cell the tissues refused to supply this nourishment. "Why do cancers start?" Dr. Wood said they were still unable to answer this question completely. Certain experiments seemed to show that a chronic irritation induced by an *x*-ray burn would produce a cancer when a person carrying that burn reached the cancer age. But there were other factors besides age, for everyone who had an *x*-ray burn did not develop cancer. In the same way they knew that ulcer of the intestine or stomach frequently, but not always, gave rise to cancers. Still they did not know exactly why irritations started a cancer. Possibly these areas got free and grew just as they would grow in a culture tube and learned to go independently of the influences which kept normal tissue cells within their natural boundaries, but this was a mere surmise. Their experimental work on animals had shown that the growing of a cancer was entirely different from the beginning of a cancer. A mouse could be rendered insusceptible to inoculation of cancerous tissue by suitable treatment before inoculation, but the same mouse might develop a cancer of its own while still resistant to implantation, so that the conditions of growth and the conditions of origin were entirely different things. It had recently been shown that a certain amount of resistance to cancer could be produced by very small doses of *x*-ray, just enough to stimulate the bone marrow and cause it to send out certain kinds of cells which had been recognized as in some way related to the spontaneous disappearance of tumors in animals, but this did not mean that the original tumor which this animal had did not keep on growing. The only way in which one could use *x*-ray or radium to treat a tumor which was already fixed and had a start was to kill the cells of the cancer and this was very difficult because large quantities of radium and prolonged exposures to *x*-rays were required, and there was always the danger of stimulating the tumor instead of killing it. Tumors spread to the body through the blood vessels or lymph channels, and this spreading could be hastened by manipulation of the tumor, as in examination, either by the patient, the physician, or the surgeon. The surgeon should be very careful in excising a tumor to go wide of the tumor itself and not to open up any of the cancer bearing tissue itself. Despite the most earnest and painstaking study by laboratory workers during the last fifteen years, the amount of knowledge acquired had been small. They had had to do a great deal of unlearning, because at first it was thought that cancer cells might grow in the same way that bacteria grew, but it had become evident that no such parallel could be drawn; the bacterium destroyed by its poisons as it grew, the cancer cell insinuated itself without causing the slightest disturbance until it destroyed some important organ or blocked the way for circulation, or nourishment. Thus it might be seen that the surface of the last great problem of medicine was still almost unscratched, and they still had no indication as to the direction in which the solution was to be obtained.

The Place of Surgery in the Treatment of Cancer.—Dr. GEORGE D. STEWART made this address. He took as his thesis "Surgery Is the Only Cure for Cancer." This he endeavored to demonstrate, speaking first of the so-called "cancer cures." These he said were so numerous that scarcely a day passed that one did not hear of a new one. The truth was that toxins, extracts, and serums had not given a single cure or, if they had cures by these means, they were as rare as spontaneous cures. The most that could be said by those who had used these methods was that they *thought* the growth had decreased in size; here too often, the wish was father to the thought. The various methods that had been used in the cure of cancer might be divided into three groups: The first group included the escharotics, the cautery, and fulguration; the second group included the radioactive agents, radium, thorium and mesothorium; the third method was by some effort of surgery. The agents belonging to the first group might occasionally cure a benign growth. When this happened the testimony of the patient so cured was sent broadcast and many flourished on this kind of exploitation. It should be remembered that drugs which caused sloughing affected healthy tissue as well as diseased tissue and one could not accurately limit the field of their action. Cauterization by means of fulguration was also a means of tissue destruction that one could not accurately control, and there were other similar methods, as the superheating method of Percy. This method was devised for destroying cancer of the cervix uteri, and was also a form of tissue destruction that was not safe. Aside from the danger of hemorrhage which Percy claimed to have overcome by cutting off the blood supply, rectal

and bladder fistulæ were not uncommon. This method was only a variant of the cautery method which had been used for some years by Dr. Burns of Brooklyn; furthermore it was only applicable to cancer of one variety. Fulguration with the high frequency current in cancer of the bladder was still extolled by some and had cured some cases in the early stage, but it had never cured a case in which the bladder wall was deeply involved. Taking up the second group of agents, radium had some very ardent advocates. In the Howard Kelly Hospital, Dr. Kelly associated with Dr. Burnham reported 1300 cases, some treated five years ago and most of them two years ago. These statistics did not carry conviction because two years was not sufficient time to say whether a cancer was cured or not. Speaking of cancer of the body of the uterus, Burnham said no case was cured, but there was a decrease in the size of the growth; it must be remembered a decrease in the size of a cancer was not a cure. Burnham said further that they would not advise radium unless operation was impossible in cancer of the cervix uteri, and that it gave the best results in cancers of slow growth. If operable, cases should be operated upon. They found radium less satisfactory in ovarian cancers. In papillomata of the bladder it had given favorable results and it had cured rectal adenocarcinoma. Dr. Stewart said he had seen two cases of carcinoma of the rectum made distinctly worse after radium treatment. The statistics given this evening showed the large number of cases of cancer of the stomach, liver, thorax, and intestines, and to these radium was not applicable. The basal celled carcinoma of the mucous membranes of the mouth were milder and more amenable to treatment than similar growths of the skin. The need was for something to cure cancer in cases in which radium did not give any help. Burnham concluded that he did not advocate the use of radium in operable cases, but only in inoperable cases and following operation. Others had found radium effective in carcinoma of the skin, papillomata, nevi, and in all superficial forms of the disease, except malignant pigmented moles in which the growth was very rapid. Albutt stated that radium had kept cases of mammary cancer alive for from three to seven years, but that one ought not to deny these patients the help that operation might offer. One must not expect too much from radium or thorium; they were effective in round celled carcoma, basal celled epitheloma, and superficial cancers of the face. It should be remembered that these were not true cancers. Koenig and Gauss, at Frieberg, after an experience with a very large number of cases stated that in carcinomas with metastases they could not report a single cure with radium, thorium or mesothorium, but they believed that these inoperable cases should be submitted to the radium treatment. After reviewing the results of still other observers who had employed the radioactive agents in the treatment of cancer, Dr. Stewart said that, summing up their evidence, it seemed that radium cured some cases of superficial epithelioma and that it had an effect on sarcoma, but that it had no effect on hard cirrhous growths. Of the *x*-ray and radium, in general it might be said that they had some curative properties, but they could not be applied in the cavities of the body and there was some question whether the *x*-ray did not in some cases have a stimulating effect upon the growth of the cells. Taking up the question of surgery in cancer, a few cases might be cited. Metropolitan Life Insurance Company showed that of 75,000 cases of breast cancer operated upon 18,000 died in one year. Lynburg reported 183 cancers of the breast, some very advanced, which were operated upon and 77 survived after three years. In cancer of the stomach Schauter reported 20 to 30 per cent. alive after three years; Altschult 14 per cent. of cancer of the stomach, and May 38 per cent. after three years. Of course it was recognized that earlier diagnosis had improved the statistics of operations, that had often been stated and would have to be affirmed and reaffirmed. It must further be emphasized that operative removal to be effective must be radical. No other method had so far succeeded in displacing surgery. Every cancer patient should be given the chance for cure that surgery held out. Cancer was a local condition only before there were any metastases, and surgery offered hope of cure provided it could be removed before that time. Those that held that cancer was a general blood disease were absolutely wrong inasmuch as it did not grow until the tumor material was transplanted to other parts of the body. If seen in the early stage radical surgical removal offered a fair prospect of permanent cure in a certain percentage of cases.

Dr. JOHN A. HARTWELL said it seemed to him that the function of the man who discussed a paper was to sum up what had been said rather than to bring out anything new. The first paper was statistical and therefore it was impossible to discuss it, but these figures in spite of what Dr. Stewart had said, were unassailable. Dr. Dublin had said that the interest in the cancer problem was not so much from the standpoint of economics as from that of sentiment. On the other hand he thought cancer took men at a time of life when they were still much needed and that the economic side of the question was very important. Dr. Wood had told them what he knew of cancer and, so far as he had been able to grasp it, their knowledge seemed to be very meagre, but they must not feel that it was through the laboratory that cancer would be controlled or mitigated. It would be in the laboratory associated with clinical work that salvation would be found. Dr. Stewart had given them the results of operative methods of treatment and had shown that there was a very much better outlook for the cancer patient through surgical interference than by any other method, yet no operating surgeon ever approached a case of cancer without serious misgivings. The surgeon got successes but he also got failures and the failures were more numerous than the successes. When one got statistics reporting 75 per cent. of cures in cancer it was well to see if there was not something that made them different from the average group of cancer case, for cancer was curable in only a small percentage of cases. A certain number could be cured if we got them at an early date. The surgeon could do little after cancer had passed the local stage. However, it was a common experience of the surgeon that early cases did remain cured. Therefore this was the line along which they must direct their efforts toward the control of cancer and the problem must be worked out by a combination of the laboratory and the clinic, by a study of mouse cancer and human cancer. The cure of cancer was not to be sought in radium or the *x*-ray though there was some evidence that these agents had actually accomplished cures; they therefore must not be set aside, but must be studied with intelligence. There was now a difference of opinion among radiologists as to the dosage and the frequency with which treatment should be given, and also with reference to the duration of the treatments and whether it should be applied locally or generally. It seemed from observations made at the Rockefeller Institute that the lymphocytes were increased above the normal by the *x*-ray treatment and the lymphocytes seemed to have an influence on cancer growth. In treating cancer by the *x*-ray or radium the patients should be observed by an expert surgeon, who by watching the results of these methods and the results of surgery would be able to make comparisons. By such a method there was reason to hope that definite conclusions might be reached and in the meantime it was well to avoid methods that savored of exploitation or that had not been well worked out.

Dr. DAVID BOVAIRD, Jr., said that if one added together the cancers of the alimentary tract, cancers of the stomach, intestines, liver, and rectum he would find that these formed about 50 per cent. of all cancers. These cases were regularly examined first by the general practitioner, so that the fate of those suffering from cancer depended upon the physician, and it was he who should be brought to an appreciation of the gravity of the situation and the need for proper action. Dr. Stewart had shown that the percentage of persons surviving operation for cancer of the stomach for from two to three years varied from 14 to 38 per cent., but such results were obtained in very few clinics in the world. A search of the literature would convince one that cancer of the stomach was one of the gravest things that could befall any one. Friedenwald of Baltimore reported 1,000 cases, 266 of which were brought to operation. Of these 138 were merely exploratory operations. The remainder were subjected to suitable operative procedures, such as gastrectomies, pylorectomies, etc., and not one of these patients was alive today. Dr. Lambert and Dr. St. John in going over the records of the Presbyterian Hospital covering operations for cancer of the stomach found 15 or 16 cases in which partial gastrectomy had been done and of these only two patients were living at the present time. One of these was apparently healthy but in the other the condition was not so clear. These were the results in most surgical clinics in this city. The responsibility

for these results did not rest on the surgeon—surgical skill does not vary so greatly in different places—but on the stage of the disease when brought to operation. As an aid in making an earlier diagnosis in cancer of the alimentary tract Dr. Bovaird urged the early and adequate use of the *x*-ray. He said he felt thoroughly convinced that the radiograph added more to the possibility of early diagnosis of carcinoma than any other one thing that they had tried in recent years. It therefore behooved them as physicians whenever they were dealing with a case of gastric disturbance not to rely wholly on the usual clinical methods but to have a thorough radiographic examination of the stomach and intestinal tract made. If that was done and the result correlated with the clinical findings the diagnosis might be made sufficiently early to give the surgeon a fair opportunity of effecting a cure. The radiograph also had a value on the negative side as well as on the positive side. It had been their experience that when a radiograph had given negative results and the patient had been subjeected to operation the radiograph was shown to be right. The radiograph could generally be relied upon to establish the diagnosis of gastric carcinoma, and when that was done no time should be lost in referring the patient to the surgeon for operation as that offered the only hope of cure.

Dr. Eugene H. Pool said it was important to define what one meant by cancer in this discussion. We had roughly two types of cancer, first, the relatively benign which rested relatively tranquil at or near the site of its inception, to this type belonged basal cell epithelioma; second, the truly malignant type, which was a creature of mushroom-like growth, a prolific breeder, a voracious and predatory despoiler and ravager. This type was represented by cancer of breast, cervix uteri and tongue. The benign type was like a cub lion which usually we might play with and fondle with impunity; this type might be treated indifferently with radium, *x*-ray, cautery, or the knife. The pathologist and the average surgeon usually could recognize clinically this type. Yet the lion cub could not always be depended upon and sometimes matured unexpectedly and caused injury and even took life. This benign type, however, was not what we had in mind in speaking of cancer in such a discussion as this. We had in mind the well defined malignant type, trifling with which was like fondling a serpent. It was unfortunate that the term cancer was used indifferently for these two types of tumor which clinically and in their life history were so different. In considering the malignant type, Dr. Pool said he had recently heard an eminent surgeon say in a carefully prepared paper, in discussing the treatment of carcinoma of the cervix with radium that in addition to numerous non-operable cases he had treated three operable cases with radium. He claimed these three cancers had disappeared and stated that this suggested that radium and not operation might prove to be the method of election in the treatment of these growths. Such was an example of the statements made by the enthusiast; one would not, however, expect such a statement from a surgeon. Such suggestions were extremely dangerous teaching. Why? Because they engendered in the mind of the sufferer a hope of success from other means than the knife; they consequently encouraged delay. Now practically the entire progress in the treatment of cancer had been dependent upon training the profession and the laity that early diagnosis and early radical operation offered the sole chance of cure. Dr. Pool claimed that radium, *x*-ray, mustard applied inside or outside, or any other pet therapeutic agent of the experimenter, commercializer, or scientist had not been put on a basis sufficiently firm to warrant recommending them to a sufferer with an *operable malignant type of cancer*. On the other hand we must continually emphasize the salutory effect if the knife was employed early. One must picture in his imagination the cancer beginning from a single cell or an extremely limited collection of cells, not initially as a diffuse lesion. Obviously if such is correct the disease may be eradicated by early operation; and more surely in direct proportion as the time of operation approached the time of the inception of the disease. Therefore we must insist that these patients be submitted to the surgeon, not only with an early diagnosis, but, better, when there was merely a suspicion of the presence of a malignant type of cancer.

Dr. J. C. Bloodgood of Baltimore said he had not come prepared to speak but to listen and to learn. However he could give a few impressions with reference to the change that had taken place not only in their knowledge of cancer, but in their attitude toward it. Dr. Wood had spoken of the workers with the *x*-ray getting cancer; workers with the *x*-ray to-day did not develop cancer. That was definite evidence that some forms of cancer could be prevented. We knew that some forms of cancer were more frequent in men than in women, in this instance the only difference was the question of the use of tobacco, and there was no reason why men should not learn to smoke without getting cancer of the mouth. Dr. Pool made the point in the difference in the results of operative treatment in early and late cancer, that was the difference between the early and late stages as far as one could tell from the macroscopical appearances. They had made a study along this line and at the end of five years compared the two groups, and there was a great difference in the results; but surgery did cure a certain number of fairly advanced cancers, though one could not put great hope in surgery in advanced cases. His figures demonstrated that education could bring to the surgical clinic cancer in their locality in a much earlier period of the disease. Their results were not due to the fact that surgery had improved but were due to the different stage of the disease at the time of operation. Their report on cases of cancer of the stomach showed three and five-year cures in 19 per cent. of the cases. In cancers of the stomach that were operable, some of which were shown to be operable by exploratory operation, in the last six years they had increased their percentage to 38 or 39 per cent. A large per cent. were living but it was not five years since all of them were operated upon. The increase, however, showed that with the education of the public and the physician in regard to the early diagnosis and the importance of early surgical interference better results could be obtained. The importance of this would be recognized when he said that 51 per cent. of these cancers were in regions in which it was difficult to recognize cancer early, and to detect the difference between advanced benign and distinctly malignant types. In a series of 2000 cases the percentage of those brought to early operation had increased from 32 to 57 per cent. From the time they began their campaign of public education until 1913 the proportion of breast lesions brought to operation early had increased from 47 to 59 per cent. These figures showed very definitely what education could do. Until six years ago they had never had an operable cancer of the right colon. In cancer of the lip, tongue and skin there must have been a period when the individual had known that he had a local affection and if he had sought treatment at the hands of the surgeon he could have been cured in almost every case. Cancers of the lip and tongue within three months had become hopeless. There was no more reason why a patient with a growth on the lip or tongue should allow it to go three or four months without seeking relief than there was why a patient with appendicitis should wait three or four days for peritonitis to set in before consulting a surgeon. The percentage of inoperable cancers that they were getting was decreasing. No one should die from cancer of the skin or lip as these were generally small growths, and they had had only about 100 pigmented mole cancers to 1500 lip and skin cases. Therefore correct information for both the public and the profession would increase the number of cures in cancer and the number of late cases would be decreased. To illustrate, breast cancer for the first time in the last five years was relatively on the decrease in the clinic in Baltimore. The laboratory workers were having a tremendous influence on the surgeons in their investigations. Surgeons had not known how to use their material for the development of knowledge of cancer. The workers in the laboratory would influence the surgeon to use their methods to advance knowledge in respect to the cure of cancer.

Poisoned Bait for Controlling the House-Fly.—Malley, in an article in the *South African Journal of Science*, refers to a mixture of sweetened water and arsenite of soda which is sprayed on detached branches of trees which have firm foliage, the latter then being placed upon strategical situations, as manure heaps and garbage cans. Other bait carriers in use are old bags and the like. Finally the bait may be sprinkled directly on the dunghills, and on the ground near by. The full formula for the bait is arsenite of sodium 1 pound, sugar 10 pounds, water 10 gallons. The insects die before they can deposit their eggs. The idea seems to have been anticipated by Berlese of Italy in 1913.—*Tropical Diseases Bulletin.*

THE PRESENT STATUS OF CHRONIC MULTIPLE ARTHRITIS, WITH SPECIAL CONSIDERATION OF INFECTION AS AN ETIOLOGICAL FACTOR.

BY GEORGE R. ELLIOTT, M.D.,

NEW YORK.

ASSISTANT PROFESSOR OF CLINICAL ORTHOPEDIC SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY, N. Y.; ATTENDING ORTHOPEDIC SURGEON, MONTEFIORE HOME AND HOSPITAL; ST. FRANCIS AND ST. JOSEPH HOSPITALS; MEMBER OF THE AMERICAN ORTHOPEDIC ASSOCIATION.

THE object of this paper is to present the subject of chronic multiple arthritis as generally accepted to-day. Prominence is given to methods that are appearing to unravel this difficult subject. We shall omit full consideration of the arthritis urica and tuberculous types of arthritis, referring to them as only part of the general subject.

To make the subject comprehensible, we shall discuss it under two chief heads or types. The two types the observing clinician would find himself dividing his patients into were he shown a large number of cases. In fact, the two main types of the older clinicians to whom we find ourselves coming back for a working basis.

Out of the great chaotic clinical mass of polyarthritis of recent years, we feel that we have something here very tangible, and a knowledge of the two chief types clearly in our mind will enable us to more clearly understand the irregular types.

The chief subject discussed in this paper is that of infection; how it plays its part.

The two types we are to consider give entirely different clinical pictures. These are: (1) Proliferating, or ankylotic type of chronic multiple arthritis; (2) degenerative or non-ankylotic type of chronic multiple arthritis.

We shall refer to the true infectious types of arthritis together with the mixed types. Out of this a working classification will be given, based on our study and presentation of the subject, which classification we hope will be understood by the physician.

1. *Proliferating, or ankylotic type of chronic multiple arthritis*, called by some rheumatoid arthritis, by others atrophic arthritis. This constitutes the large class of polyarthritis now being studied as never before, attracting and engaging the attention of world-wide laboratory research. It attacks as a rule the young adult; its febrile onset is irregular and frequently entirely overlooked; its best external signs are seen in the small peripheral joints which tend to become fusiform in shape; it is apparently steadily progressive; ankylosis tends to occur and the patient becomes bedridden. This type of patient may linger on for years, a hopelessly deformed invalid, dying finally of cardiovasculorenal disease with profound anemia. Even at this day such in brief too truly pictures a large class now filling our institutions for the treatment of chronic invalids and private homes throughout the land.

As a result of intelligent research now going on this picture is changing. We are rescuing patients and staying the progress of the disease, cutting it short so to speak and repairing damage done. In a certain way, we may compare this disease with poliomyelitis. In the latter, however, we have a distinct infection doing its work quickly and ceasing action. The resulting damage is left to nature and the surgeon for repair. In chronic multiple arthritis, on the other hand, the active agent seems to act intermittently, but no less effectively, and the semblance of progression characterizes the clinical picture. The etiological factor stamped out, however, and the polyarthritic becomes as the poliomyelitic amenable to the restorative power of nature and the intelligent properly directed skill of the surgeon. All this leads us at once to infer that at the etiological root of this type of arthritis lies an infection—the generally accepted view to-day.

What is the basis for accepting belief of infection? In order to comprehend the nature of the evidence forcing upon us the infection theory of polyarthritis, an understanding of the nature of some of the comparatively recent work done in rheumatic fever is necessary.

Of the several promulgated theories of the etiology of rheumatic fever only two schools appear to meet with recognition: One that it is a specific disease due to a specific germ; the other that there is no specific organism but a form of septicemia of staphylococcal or streptococcal origin, and bearing a close analogy to pyemia. Much has been produced in the support of both of these views.

Regarding the single germ theory, which now seems the favorite, several workers have isolated a specific germ and confirmed the specificity through cultural inoculations. Achalme, in 1891, discovered a bacillus. Triboulet, in 1897, isolated a germ from the blood in rheumatic fever, and grew it anaerobically. In 1899, Westphal, Wassermann and Walkoff published their findings regarding a diplococcus. Soon after this, Poynton and Payne began to publish some of their research work along this line describing a germ isolated by them—a micrococcus identical with those of other observers. To Poynton and Payne we are indebted for a mass of work which has excited a great deal of scepticism among laboratory students. Many have failed in any way to duplicate their findings. This has led to their work being discredited by some. But just now it can be safely stated that their work is being recognized, and of great assistance in bringing to

the front much to support the single germ theory of acute rheumatic fever, and that germ a micrococcus identical with that discovered and described by Triboulet and by Wassermann and more recently by Rosenow. All the observers point out the extreme difficulty in isolating the germ, and here doubtless is the explanation of so many failures on the part of laboratory workers who have made their cultures from the blood stream and joint cavities.

It is not in the joint cavity for example, the place usually examined, that organisms are found. The joint effusions both in rheumatic fever and in arthritis experimentally produced are usually sterile. It is in the areolar tissue about the joint—that binding the endothelial tissue to the fibrous capsule, the site of cellular exudation—where the organisms are found. The organisms find difficulty in getting into the free-joint cavity in any numbers. They here encounter the endothelial cells and leucocytes and are rapidly destroyed. They locate themselves then outside about the joint, and

FIG. 1.—Proliferative or ankylotic type of chronic multiple arthritis. Age of patient 27 years. Onset of disease at age of 20 years. Illustrated further by *x*-ray, Figs. 2 and 3.

it is just this fact that has made the bacteriological study of joint infection so difficult and so long in being understood. It opens to us, as we shall show later, a better means of understanding chronic polyarthritis. The blood stream is simply a carrier containing only now and then organisms gathered from the original focus of infection; hence also the repeated failures in getting a specific blood culture. This definite organism has been isolated from the human subject afflicted with rheumatic fever and injected into rabbits producing a disease identical with that in man; the microorganism has been recovered and again injected. This has now been confirmed by many observers (Triboulet, Wassermann, Poynton and Payne, Rosenow and many others).

Evidence Supporting the Teaching of the School Advocating the Septicemic Theory.—Kronenberg, in 1889, expressed the view that rheumatic fever is not a disease sui generis, but rather a reaction of the joints and other tissues to a series of bacterial influences, *e. g.*, streptococcal, staphylococcal, gonococcal and allied infections. Those holding this view were confronted with absence of suppuration characterizing its clinical manifestations. This absence is striking. Frequently in rheumatic fever the reaction is pronounced, and the febrile movement marked, yet suppuration is rare.

To meet this absence of suppuration, it became necessary to attenuate the organism and speak of attributes which had ceased to be pus-producing. This pyogenic germ in its transformation to a joint environment must have materially changed its attributes and ceased to be pus-producing. This is especially interesting, and has an important bearing in chronic multiple arthritis, as we shall see later.

How the Theory of Infection is being Worked Out; Meaning of Mutation, Focal Infection and Elective Localization.—As we have just stated, since the pus-producing organisms have played the chief rôle in the rsearch work of arthritis, it has become necessary to modify in some way the specific attributes of the organism. And we have referred to the recognized attenuation need of the pyemic school. To explain this attenuation gave rise to the use of mutation and focal infection. Herein lies much that is promising toward the solution of our arthritic problems.

MUTATION.—The repeated failures to obtain cultures from the blood and joint cavities in active forms of rheumatic fever led bacteriologists into side fields of investigation. Ruediger,[1] in 1906, called attention to fermentation and morphological changes of certain streptococci; later noted by Buerger and Rittenberg,[4] Anthony,[2] Walker,[3] and others. Davis,[6] after a great deal of work, stated that transformation of one member of the streptococcus group into another within certain limits appeared to be not an uncommon phenomenon. Rosenow[6] says: "Davis and Rosenow have shown that the encapsulated streptococcus from "septic sore throat" can be converted into streptococcus mucosus on the one hand and hemolytic streptococcus on the other." Rosenow also calls attention to a previous paper where he has shown that streptococcus viridans isolated chiefly from the blood in cases of subacute endocarditis may by animal passage take on the properties of the typical pneumococcus.

He summarizes thus: Altogether twenty-one strains isolated originally as hemolytic streptococcus from a wide range of sources, including erysipelas, scarlet fever, puerperal fever, arthritis, tonsillitis, etc., in one way or another, have been converted into *streptococcus viridans;* 17 strains isolated as *streptococcus viridans* chiefly from the blood and tonsils in cases of infective endocarditis have been converted into pneumococci. Eleven strains isolated from the sputum, blood and lung in pneumonia and empyemia have been made to correspond to hemolytic streptococci. The streptococci from three of the strains acquired all the essential features of the streptococci of rheumatism, two into hemolytic streptococci, the streptococcus of rheumatism, *streptococcus viridans* and back again into the pneumococcus. Rosenow asserts that the various strains of the streptococcus group may be converted each into the other.

Here then the change appears as nothing short of a real mutation. To enable one to grasp the subject intelligently, it may not be amiss to refer to what biologists mean by mutation. Like pre-

Raphaelism in art, the mutation theory is a revival, so to speak, in a new dress of the theory of the origin of species of pre-Darwinian times. The terms mutation, mutability, immutability, etc., were completely driven out of use by the theory

Fig. 2—Radiogram of left hand of patient shown in Fig. 1. Note selective character of the disease in the hands—proximo-medial joints chiefly; also great amount of destruction.

of natural selection. While Darwin used the term mutability, he used it in a restricted sense from that of the modern biological school of mutation. Mutation in the modern sense means that species arise by saltations or jumps, and these individual saltations can be observed like any other physiological process. These saltations or mutations occur without transitional gradations. This is readily seen to stand in marked contrast with the generally accepted selective theory that species of animals and plants have arisen by imperceptible gradations, the changes being so slow that the life of a man is not long enough to enable him to witness the origin of a new form. The mutation theory means that the attributes of organisms consist of distinct, separate and independent units. Each new unit, forming a fresh step in this process, sharply separates the new form as an independent species from that from which it sprang. The new species appears all at once. It originates from the parent species without any visible preparation, and without any obvious series of transitional forms. Natural selection, Darwin says, chooses "slight variations." Natural selection, he says, works on "chance variations" (Life and Letters, II, page 87 et seq.). Unless such occur, natural selection can do nothing ("Origin of Species," p. 64). Wallace is still more precise than Darwin in his selective theory. He dwells upon rapid multiplication and the premature death of innumerable individuals; variability and survival of the fittest. He says: "It is therefore proved that if any particular kind of variation is preserved and bred from, the variation itself goes on increasing in amount to an enormous extent, and the bearing of this on the question of the origin of species is most important."

Without going further into the details of the selection theory, it holds that "species have arisen by natural selection resulting from the struggle for existence" requiring long periods of time. According to the theory of mutation, species have not arisen gradually as the result of selection operating for hundreds or thousands of years, but by sudden, however small, changes. De Vries'[1] experimental work with the primrose (*Oenotheria lamarkiana*) is interesting as well as illustrating the full meaning of the mutation theory as set forth by one of its chief exponents. DeVries brought over 100 plants into cultivation, and only one, as he terms it, was found passing through the mutation period. In seven generations his experiments dealt with 50,000 plants and of these over 800 mutated. As a result of these experiments, DeVries formulated laws, some of which are here given:

1. New elementary species arise suddenly without transitional forms.
2. New elementary species are, as a rule, absolutely constant from the moment that they arise.
3. Mutability appears periodically.

So much for the mutation theory which has by no means been fully accepted by the great class of biologists. This lack of acceptance applies also to the special primrose work of DeVries just alluded to.

Fig. 3.—Radiogram of right hand of patient shown in Fig. 1. See also Fig. 2.

While the work of the bacteriological transformationists fails in certain important facts in meeting the strict requirements of the mutation school of biology, yet it is clearly seen that they fall back upon that school for any approximate scientific ex-

planation of their experimental findings. This is not the place to discuss the biological placing of the bacteriological mutationists, but it is well to observe that the claimed attributes of bacterial organisms do not arise in accordance with some of the established laws of the mutation school —one especially that "new elementary species are as a rule absolutely constant from the moment that they arise." This constancy is dwelt upon with no trace of reversion. But, according to Rosenow, especially members of the streptococcus group are by means of oxygen regulation and animal passage made to pass one into the other in a sort of "Jack-in-the-box" manner—now I am hemolytic and now I am not, and now again I am hemolytic; now I am soluble in bile and now I am not. Rosenow's changes occur practically over night.

It is interesting right here to mention the tenacity with which some bacteria cling to their attributes. Quite recently Dr. Rufus Cole of the Rockefeller Institute told me that one of his well-known types of pneumococcus had at that time made 226 animal passages, with complete retention of all its attributes and without change. It had not, however, been subjected to the Rosenow technique or mutational experimentation. This is of interest only as showing the stability of this particular member of the streptococcus group, and in no manner is intended to reflect upon Rosenow's work.

We have especially emphasized the "species" and what a change of this means. It may be found that the changes are not so great after all. That the organisms are all of the same species and only variants; that, for example, the *Streptococcus hemolyticus, Streptococcus mucosus, Streptococcus pneumococcus, Streptococcus viridans*, are all variants of the same species. This is much easier to reconcile with the rapid changes resulting from changed environment. We must await further development and confirmation to clear up the subject and make for a complete reconciliation with the established laws of biology.

And now to the practical work of the bacterial transmutationists along this line. The following table by Davis[5] showing the relation of streptococci is interesting at this point.

Relation of Streptococci

Organisms	Hemolysis	Green Colonies Blood Agar	Capsule	Solubility in Bile	Inulin Fermentation	Exp. Arthritis	Exp. Endocarditis
1. Str. hemolyticus	+++	0	0	0	0	+++	±
2. Str. epidemicus.	++	0	+	±	0	+++	+
3. Str. mucosus.	±	++	+++	+++	++	++	±
4. Str. pneumoniae	0	+++	+	++	++	±	+?
5. Str. viridans	0	+++	0	0	+	±	+++

Sign — indicates particular property may occur rarely or to a slight degree.

Sign ± gives a general idea of intensity of frequency of the property.

The plus signs give general idea of the intensity or relative frequency of the property. The first members of the group are hemolytic. Descending the series, this property vanishes.

The relative solubility in bile of this group of organisms first called attention to by Neufeld in 1900, is regarded as of much value in differentiating. The bile solubility and hemolytic attributes may be styled the two chief factors making for differentiation. To make a hemolytic become a non-hemolytic, for instance, is certainly striking.

To bring about the transformation Rosehow devised a certain technique. The fact that lesions in rheumatism occur in relatively nonvascular regions suggested to him that the infecting organism might be sensitive to oxygen pressure. To meet this he made his inoculations into tall tubes containing acites-dextrose agar. Thus giving near the top of the tube aerobic conditions and near the bottom anaerobic. He found that the oxygen requirement was the chief factor, since the largest number of colonies developed between 1.5 cm. from the top and 3.5 cm. from the bottom of the tube. He further found that growths in symbiosis with other bacteria, and injection into cavities in animals called forth mutational forms. Rosenow's work is most interesting and it is well to note how he adapts his experimental transitional work to the practical solution of the arthritic problem.

Fig. 4.—Proliferative or ankylotic type of chronic multiple arthritis. Patient aet. 27 years. Onset 2½ years ago, immediately following pregnancy.

Davis[5] states as a fact "that injection of *Streptococcus hemolyticus* intravenously into a rabbit practically always gives rise to arthritis and tenosynovitis which may be monoarticular or polyarticular. When given in moderate doses rarely do the streptococci localize elsewhere. In large doses prone to produce myocardial abscess and hemorrhages."

Rosenow[6], through his technique, has obtained three types of cocci from the joints in rheumatism. One type corresponds with that found by Poynton and Payne and might be called *Micrococcus rheumaticus*. Another type corresponds to the description of Beatty and might quite properly be designated as *Diplococcus rheumaticus*. And a third group, which forms long chains and may be designated as *Streptococcus rheumaticus*. All types are quite susceptible to phagocytosis and probably have not the power to grow in the free circulation. In from 24 to 48 hours after a large intravenous injection in rabbits and dogs the blood is sterile. The affinity of the *Streptococcus viridans*, especially as

isolated from cases of chronic infectious endocarditis, for the endocardium of animals and of the hemolytic streptococcus for the joints is now well established. Rosenow has been able to produce endocarditis and arthritis in the same animal by injecting mixed cultures in pure form.

FIG. 5.—Proliferative type of chronic multiple arthritis. Advanced type. Male aet. 56 years. Onset at 24 years. Note especially selective character of this type involving chiefly the proximo-medial joints. Also note comparatively good condition of other finger joints after 30 years. Note also that in this very advanced case joint destruction is not much greater than in the case of comparatively short duration. (Figs. 1-3.)

The arthritis is multiple, never suppurative. The endocarditis produced from the strains from rheumatism, just as has been found to be the case in *Streptococcus viridans* is embolic in origin.

Rosenow found virulence of his three types of a low order. When first isolated all are characterized by a marked capacity to multiply at a low temperature and all very sensitive to oxygen pressure. He makes the following statement: "Strains of the three varieties have been converted each into the other." By means of animal passage strains of each group have been converted into typical pneumococci. Rosenow in his rheumatism experiments confirmed also the findings of Beattie and Poynton and Paine that a low temperature favors their growth. This is in keeping with the well-known clinical fact that cold aggravates the symptoms in rheumatism. Rosenow's experimental work suggested to him the reasoning that cold causing vasomotor constriction might favor the growth of organisms by causing a lack of blood and leucocytes and in consequence a lowered oxygen pressure.

The results, then, of cultures in man and of the animal experiments support the view that acute articular rheumatism is due to streptococci having peculiar properties. The workers have found that affinity for joints, endocardium, pericardium, and muscles characterizing these organisms when isolated tends to disappear on cultivation. It may be restored by animal passage. When the rheumatic strains have acquired the cultural features of hemolytic streptococci they lose the affinity for the endocardium and pericardium and acquire an even greater affinity for the joints.

Focal Infection and Elective Localization.—The literature for a considerable time has been filled with infective data and attempts at localization as the underlying cause of arthritic involvement. The tonsils, the oral cavity, especially the gums and teeth with concealed abscess cavities, have given us from both dentists and physicians a real bombardment of literature dealing largely with clinical observations and rather positive statements; yet beyond the localization of the foci very little real scientific data. No inconsiderable part of this literature deals with cultures taken from the mouth—alveolar cavities, tonsillar crypts, etc.—so-called autogenous vaccines made and injected into the patient. In the light of our present knowledge such superficial work only does ill to the patient and reflects upon the scientific bateriological knowledge of the physician. It is needless to say that to be of any promise whatever autogenous vaccines must be obtained from closed cavities under proper aseptic precautions. Many workers are now adhering to this and the results are more promising.

Focal sites in connection with the teeth illustrate this part of the subject well and we reproduce here some of these concealed foci.

The nasal sinuses have attracted a great deal of attention, the appendix, the seminal vesicles, the intestines—all these and many more have figured as sites of focal infection. That such focal sites exist as points of toxic entrance has long been known, but it remained for Rosenow to emphasize something that had escaped recognition—that focal sites furnished a place where bacteria may acquire new properties. These new properties are in keeping with those of the transmutationists already mentioned.

It is believed that previous to an attack of rheumatism various types of the streptococcus group, especially the hemolytic streptococcus, acquires in the tissues of the infected individual the factors which give them the affinity for joint, endocardium, and

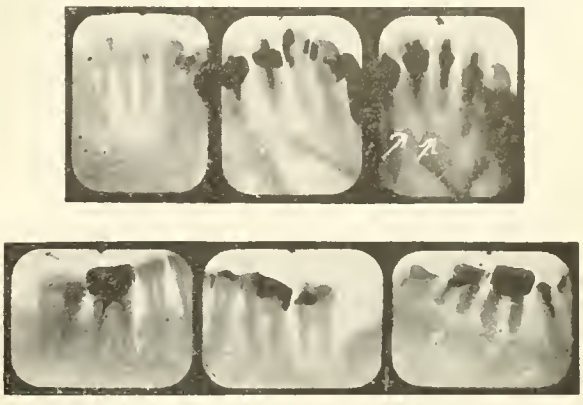

FIG. 6.—Dental roentgenograms for publication of which I am indebted to S. M. Getzoff, D.D.S., N. Y., showing concealed septic foci. Apical abscesses and resultant bone atrophy are well shown. Also stripping of roots from pyorrhea. Note especialy the concealed foci which here were due to failure to empty and fill the canals.

pericardium. These cavities so to speak, are human test tubes in which many of the mutation experiments outside the body are duplicated. In short, the streptococcus in these concealed cavities under low oxygen pressure and in the presence of other bacteria loses as it were its virulency and acquires

new properties, giving it a special affinity for joints and endocardium or joints alone, as the case may be.

The intestinal tract has long been looked upon as a focal site. Experiments have shown lesions of

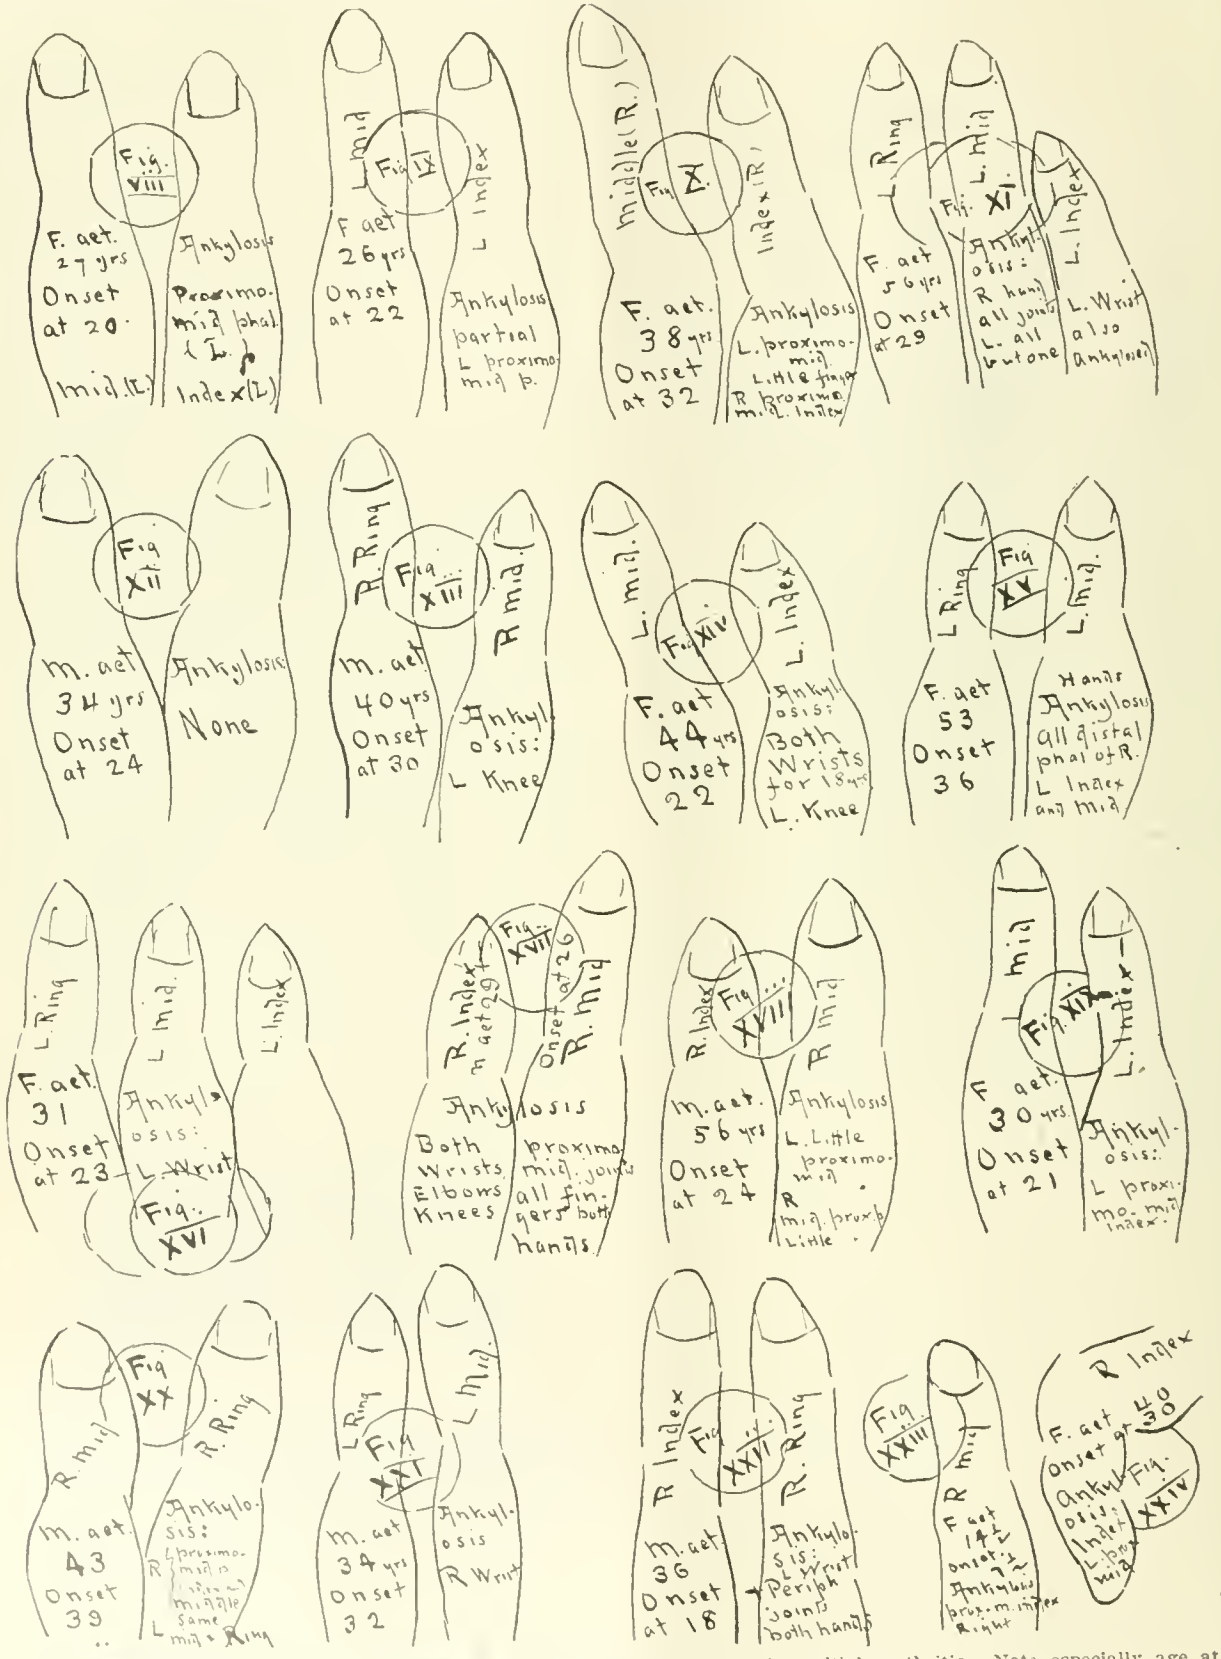

FIG. 7.—Tracings illustrating the proliferative or ankylotic type of chronic multiple arthritis. Note especially age at onset and ankylosis. Also the spindle shaped proximo-midphalangeal joint—the so-called Haygarth nodosity. Note also the large percentage of males. Cases not specially selected. We have complete *x*-rays, photographs, and casts of hands from which above are taken

the appendix, diarrhea due to cellulitis, ulceration, and the enlargement of the mesenteric glands (lymph) observed commonly in animals after intravenous injections of streptococcus strains indicate that the organisms may gain entrance into the lymph structures of the intestinal tract.

Subinfection.—Adami[10] covers a part of the field of infection in a way that seems worthy of a great deal of consideration and can be corelated with that which has gone before. Much of his work may bet-

ter belong to the non-proliferative type of arthritis, to be referred to later, but it is of practical interest right here inasmuch as he is dealing with infection. He, too, has recognized the fact that the bacteria in the more chronic manifestations under consideration are changed; have lost some of their attributes. The streptococcal group is especially mentioned. He says: "Fourteen years ago I showed that lymph nodes of the respiratory and alimentary tracts in normal animals constantly afforded cultures of pathological and non-pathological bacteria; that through leucocytes bacteria are constantly being carried into the system and constantly being destroyed in the healthy animal. That with inflammatory conditions in the alimentary canal and greater accumulation of leucocytes in its walls there must be greater passage of these from the surface into the system. According to virulence these set up other foci of active infection or a condition which I term subinfection." He distinctly states that bacteria so carried do not set up suppuration—a fact all intelligent observers have noted. Adami says the bacteria do not accumulate to any extent but die with liberation of toxins. These toxins cause a poisoning of the tissue cells in which they lie and through reactive stimulation a replacement by fibrous tissue. That tuberculous and other bacilli fed to the young animal by mouth are found in the thoracic duct one to two hours afterwards. That by the eighteenth year whether point of entrance is the respiratory or alimentary tract 95 per cent. of persons examined respond to tuberculo-cutaneous tests, though only 10 per cent. die of the disease. In 85 per cent. of the population the disease becomes arrested and latent.

Coordination of Foregoing Views.—From the foregoing it has been seen that the views of the different workers can be largely reconciled, and although traveling different roads they ultimately appear to meet. They all have recognized the need of getting rid of the pus-producing attributes of the organism with which they worked. Poynton and Paine, Wassermann, Walkoff, and others found it unsatisfactory to try to get any real cultures from the joint cavities or blood. That the joint effusion is frequently sterile. They went outside the joint cavity in the areolar tissue, in connective tissue attachments, in the *non-vascular* spots. Here they found the bacteria thriving best; from this source they made their cultures. From these points they obtained bacteria whose attributes had in a measure been changed.

The mutationists also recognized the need of in some way changing the attributes of the organisms of the streptococci group and especially the pus-producing factor alluded to. Rosenow conceived the idea that a low oxygen pressure might account for the changed attributes of the organisms. That if a number of the streptococci were made to live in anærobic rather than aerobic conditions, the proper selective affinity for joints and certain other tissues might be brought out. That through concealment in human test tubes, such as an apical abscess cavity of the tooth, an enclosed circumscribed pocket in a tonsil or appendix, the proper selective qualities of the organisms were brought out. To duplicate this in the laboratory Rosenow devised the experiments and technic alluded to above. All this is readily seen to reconcile itself with the avascular findings of Wassermann, Walkoff, Poynton and Paine, and others.

Further, Adami's findings in a measure, too, can be reconciled with these views. He follows the line of changed attributes of his organisms and deals with it in his so-called subinfection. So much for the working out of the bacteriological etiology of the subject along lines that ultimately coordinate.

Further Observation Bearing on the Subject of Infection (*Myositis* and *Fibrositis*).—The physician is constantly called upon to treat some localized muscle pain, especially at or near its tendonous insertion or some hardness in the muscle substance and we have long sought for a rational pathological explanation. Recently Rosenow has produced experimentally such myositis and given us a rational explanation. He produced lesions in numerous rabbits, dogs, and one monkey. In no instance was there suppuration. In order for the non-virulent strains of streptococci to localize in the muscles he found 12 to 21 animal passages necessary. When the various strains produced myositis their affinity for the muscle was so marked that each of the series of animals developed lesions in proportion to the dose.

A study of a section of muscle showed: (1) A small hemorrhage; (2) muscle fiber becomes granular and breaks up into fragments as a rather sharp leucocytic infiltration appears. The number of organisms are greatest at this time, after which they gradually disappear without causing suppuration. The leucocytes now give way to larger mononuclear cells, and as connective tissue is being formed there is found a deeply basic staining material in which bacteria are no longer demonstrable.

Adami says that this is the very thing he has been calling subinfection results—a chronic interstitial fibrosis, as he styles it. Streptococci of a particular grade of attenuation become arrested in the muscle capillaries, more especially those situated near the tendinous attachments.

Infection as Related to Certain Recent Etiological Theories of Chronic Multiple Arthritis.—The joint lesions of chronic multiple arthritis are commonly destructive and pronounced. There is frequently so much loss of bone and cartilage or formation of new bone that the blood-vessels have figured as playing the chief rôle. Wollenberg[11] especially has dwelt upon disease of the blood-vessels supplying the joint as explaining the lesion. The disturbed balance between arterial and venous supply causing the regressive and progressive changes characterizing the anatomical picture. In short, a localized arteriosclerosis.

Much discussion has arisen over the arteriosclerosis finding. Arteriosclerosis is commonly found in advanced cases of chronic multiple arthritis and by most observers believed to be a secondary finding. Even Wollenberg, the author of the so-called "vascular theory," does not claim that the sclerosis is primary, but that it stands as a "middleman" through which traumatism and inflammation produce the characteristic lesions of chronic multiple arthritis. Wollenberg has produced animal experiments upon which he largely bases his views. Walkhoff, Ewald, and Preiser[12] have repeated his experiments and are unable to corroborate his findings. Wollenberg's admission of inflammation necessarily restricts his theory to explaining the grosser findings only.

It remained for Rosenow[13] here to give the blood-vessel disease a logical cause and establish the blood-vessel lesion as primary, and primary through the source of infection. He found microscopic sec-

tions of tendon muscle and thickened capsule examined in a number of cases of chronic multiple arthritis showed marked thickening and not infrequently complete plugging of the blood-vessels apparently not the result of organized thrombi but rather of a primary endothelial proliferation. Bacteria were found in these areas of endothelial proliferation. In rabbits the exudate in the joints after intravenous injection and in the abdominal cavity after intraperitoneal injection usually show a preponderance of endothelial cells. For these reasons Rosenow regards the changes observed in the blood-vessels as primary rather than secondary. He says: "It would seem as if in arthritis deformans (chronic multiple arthritis) the microorganisms are taken up from the circulation by the endothelial cells which proliferate freely so that eventually the blood supply is reduced or cut off, in consequence of which there result areas of lowered oxygen tension, diminished nutrition, and atrophy." Such conditions would favor the growth of organisms which on isolation are sensitive to oxygen. He has found clumps of old bacteria, some alive, in the thick layers of old fibrous tissue in the capsule of the joints in which there was no sign of recent inflammatory reaction.

If these findings of Rosenow regarding the primary pathological origin of the joint blood-vessels are fully confirmed and accepted, much of the disputed anatomical picture of chronic multiple arthritis will be thoroughly cleared up.

The Rôle Infection Plays in Producing Lesions of the Nervous System in Chronic Multiple Arthritis.—For years many writers clung to a nerve origin for so-called arthritis deformans. This was largely based upon the rather bilateral nature of the arthritis. A great deal was said about the probable implication of anterior horn cells, motor and trophic. This theory has gradually fallen into disuse and can be said to be practically dropped. The arthritis is not alway bilateral; in fact, often very irregular in its distribution. The past few years have brought forward a new theory which clinically has been generally accepted. This has come with the generally accepted view of the infective etiology of arthritis—that the organism causing the arthritis may also attack the nervous system; that a common infection is the cause of the different lesions. Poynton and Paine, Triboulet, and others have dwelt upon this. Triboulet's[3] case which he reports with autopsy illustrates this very well.

The patient, a woman aet. 19 years, afflicted with chronic multiple arthritis complicated with nerve and muscle findings. He found degeneration of the lumbar posterior nerve roots and the resultant degeneration of the posterior columns of the spinal cord the result of a localized meningitis. The history showed that both the arthritic and neural changes were the common result of a puerperal infection.

This case, supported by similar findings by other authors, strongly supports the belief that both the nerve and arthritic phenomena of chronic multiple arthritis are the result of an infection having special affinity for these structures. Recently Dr. P. W. Nathan presented before the New York Neurological Society some of the results of experimental work he had been making along this line. His findings are striking, and corroborate the clinical findings referred to and strongly support the belief above expressed.

Where Does the Theory of Infection Logically Lead Us in Classifying Our Cases of the Proliferation Type?—We see, then, how far-spreading the subject of infection becomes the moment we begin to deal with the organism changed, attenuated, or mutated, as the case may be; that the organism in the vicinity of the joint active is quite different from the organism when originally produced and imprisoned in its cavity, be that connected with the teeth, tonsil, appendix, or elsewhere in the body; that in its cavity it has acquired new attributes, and as a joint invader it takes up a new life. It has been suggested that the common failure of autogenous vaccines is attributed to this very fact; that a vaccine made from the organism at the focus of origin is useless against the organism after it has acquired the new life and in action about a joint.

The question is often asked, if we accept the view that chronic multiple arthritis has an infectious origin, how do we know that it is not, after all, a late manifestation of acute arthritis? In other words, if we admit an acute rheumatism of infectious origin is chronic multiple arthritis, not, after all, a chronic rheumatism? Some hold this view, and much can be said in its favor.

It would appear that the text-books have long erred in teaching that little permanent damage is done to the joint tissues by the lesion of rheumatic fever. Experience teaches us that there are different types of the disease which seem to grade imperceptibly one into the other, giving markedly different local conditions and constitutional results. English authorities, for example, recognize three distinct types without entering the so-called rheumatoid field:

1. Where the organisms first gain access to the synovial membrane by means of the blood stream which do not get through the endothelial into the joint cavity. The connective tissue is swollen, the blood-vessels distended; even exudation occurs; but the organisms ultimately are destroyed by the endothelia and leucocytes, absorption takes place, and the function of the joint is restored.

2. The arthritis is more severe. Tendon sheaths in the neighborhood are implicated. The endothelial synovial lining becomes damaged and a certain amount of joint exudation occurs. For a long time the joint remains stiff.

3. Process less acute. A cellular exudation occurs around the blood-vessels and arterioles, producing what is called a perivascular fibrosis. Contraction follows, tending to diminish blood supply and nutrition of the synovial tissues, explaining probably the clincal phenomena such as feeble circulation in such joints, dropsical condition, slow reaction to all treatment. Effusion is passive here, hence cultures negative.

If such a pathological picture is accepted for so-called rheumatic fever, then it would seem but a step to enter the field of chronic polyarthritis and see one condition after another engrafted upon it, depending upon the attenuated or mutated organism acting; the resistance offered by the patient; the factors of trauma, of static disturbance, of arterial involvement, and of consequent joint changes.

We have, however, no such proof limiting the chronic types of arthritis to a single organism, as in rheumatic fever. On the contrary, there is much pointing to the probability of its multiple origin from many germs.

We know that arthritis is produced by several infections, such as gonorrhea, puerperal infection, influenza, and allied diseases. These are usually regarded as due to a distinct invasion of the organism, producing a rather violent reaction commonly to the extent of pus producing, and are to be considered later under a separate heading. On the other hand, chronic arthritis is the resultant of the organism attenuated, mutated through elective localization—a variant or mutant of the original.

It is not generally conceded that there is any external expression by which we can diagnosticate the particular organism acting. After showing one of our well-known surgical teachers a series of cases of chronic multiple anthritis he asked, "Now please show me a well-marked syphilitic type." If we exclude the arthropathy of locomotor ataxia it is quite impossible to make such a showing. In the present state of our knowledge on the subject the external joint expressions of most of the forms of chronic multiple anthritis are not distinctive enough to make an etiological-organism diagnosis, tuberculosis excepted.

We confidently expect that the classical type with which this paper deals will ultimately give such a showing. That is to say, with our increased understanding we shall be able to recognize it. We will allude to this later. At the present time, then, many hold that the primary etiology of chronic multiple arthritis is due to a variety of organisms, the streptococcus group, with its variants, being by far the most common. Some think that, like rheumatic fever, chronic multiple arthritis will ultimately be found due to a single organism, and are working to that end.

There is no doubt that we have many different types of chronic multiple arthritis where different organisms have played an etiological part. We are able to separate many of these and set them apart as types of chronic arthritis. In the midst of these types we have stood confused. To the observing student, however, there remains one type having a rather clean-cut clinical history with a clean-cut external joint picture. It is the type I have illustrated by photographs and drawings in this paper—the proliferating or ankylotic type. We believe that signs point here to a distinct entity—that entity may mean the streptococci group and variants or one member of the group.

In a second paper we shall deal with another striking type of chronic multiple arthritis referred to in the beginning of this article—the so-called degenerative type. In this latter type infection proper is a doubtful factor.

MALIGNANT TRANSFORMATION OF BENIGN INTESTINAL GROWTHS.*

By Frank C. Yeomans, A.B., M.D., F.A.C.S.,
New York.

The benign tumors of the colon and rectum to engage our attention are of the polypoid type and appear clinically as the solitary polyp, multiple polyposis, multiple adenomata and villous tumor. All of these growths have a common origin from the mucous membrane and both in children and in adults are of the same histologic structure, namely, glandular with connective tissue intermingled. They differ only in form (sessile or pedunculated), in number and in size, and in the relative amounts of glandular and of fibrous tissue present.

The etiology of these growths is shrouded in the same gloom as is the true cause of cancer itself. Meyer holds that multiple adenomata are due to congenital malformation of the connective tissue of the mucosa and submucosa of the bowel wall; that the epithelial changes are secondary, inflammatory in nature, and not due to a disturbed physiology. Liebert and Schwab concur in the opinion of Meyer that connective tissue proliferation is primary but consider it due solely to chronic irritation. Their examination showed that the process was independent of the epithelium and began by the formation of new blood vessels in the connective tissue.

G. Hauser, on the other hand, basing his observation on four cases of multiple adenomata, all of which were combined with carcinoma, three in the rectum and one in the sigmoid, states that proliferation of the mucous glands is primary and influenced by chronic irritation, though this may not be the only cause. The glandular epithelium loses its differentiation and physiological function and is replaced by degenerated and physiologically indifferent epithelium.

H. C. Ross (Induced Cell Reproduction and Cancer, 1911) observed *in vitro* leucocytes divide after absorption of certain chemical agents. The active agents or auxetics he employed are contained in the remains of dead tissue, namely kreatin, xanthin, and globin. Rose says: "Irritation is always followed by cell proliferation. Irritation means damage and damage means cell-death. Cell-death sets free kreatin, xanthin, and other auxetics, and the cell proliferation is caused by their absorption by the neighboring living cells. Cell-division is apparently an automatic phenomenon in the sense that the death of one cell will cause the reproduction of its living neighbors. The knowledge that dead tissues cause cell-proliferation is sufficient to give an inkling as to the cause of benign growths. Supposing for some reason, such as a slight injury, a local cell-death takes place, it would cause increased proliferation of local cells, and so form the basis of a tumor. Once this growth started, it will go on until, by causing "irritation," or to be more accurate, extensive cell-death, it may now induce the cell-proliferation of healing around it, and so, by the formation of connective tissue, cause its progress to be arrested by a capsule." He cites in illustration the formation of fibroids of the uterus.

The different theories of causation would be of academic interest only, were it not for their bearing on prognosis. Clinical experience, I believe, justifies the opinion that most of these tumors are inflammatory in origin. As evidence of this is the

*Read at the eighteenth annual meeting of the American Proctologic Society, Detroit, June 12, 1916.

frequent history of dysentery or colitis preceding the development of adenomata. Ball states that the ova of *Bilharzia hæmatobia* deposited in the mucosa may give rise to adenomata and that other intestinal parasites may produce new growths by irritation.

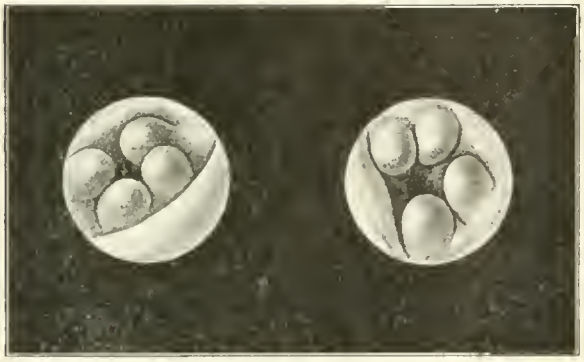

FIG. 1.—Multiple adenomata of the colon as seen through the proctoscope.

Positive evidence of the rôle of irritation in the causation of multiple adenomata is also furnished by therapy. In some cases retrogression and disappearance of the growths have followed the removal of the irritating substances by colonic lavage. In other and more resistant cases, diversion of the fecal current and irrigation have been efficient. As an example of the latter is the following case:

Mr. T., aged 30 years, referred to me in August, 1913. Fourteen months earlier he had suffered an attack of diarrhea, lasting four months, relieved by medical treatment. He remained well about six months when the diarrhea returned and had persisted four months when he first visited me. Movements then occurred hourly by day and once to three times at night, and contained considerable mucue, pus, and blood. His weight-loss was ten pounds, he was anemic and felt very weak. Proctoscopy showed typical multiple adenomata, the growths mostly sessile and varying in size from a pea to a hazelnut, extending beyond the reach of the tube (Fig. 1). During the next month he lost ten pounds in weight in spite of local and constitutional treatment, and I then did a colostomy in the transverse colon, no tumors being palpable above the sigmoid. Unfortunately when the bowel was opened on the fifth day it was found that the adenomata extended to the hepatic flexure and presumably to the cecum. By irrigations through the colostomy the greater number of growths below the artificial opening have disappeared, while retrogression has occurred in those remaining. Those growths above the colostomy have to a lesser degree been influenced by the operation, yet the patient's bowels act only once to thrice daily, he has regained his strength and most of his weight, has lost his toxemia, and is regularly employed as an elevator man. There is no evidence of malignancy.

Malignant transformation.—The answer to the question of why benign growths change into malignant ones is as of absorbing interest as is the enigma of cancer. That such transformation occurs is beyond cavil. Charles W. Cathcart illustrates such transformation admirably in his illuminating work on "Innocent and Malignant Tumors," 1907. He chose bony, cartilaginous and medullary neoplasms. In each class the growths were arranged in gradation series from innocent to malignant. He concludes that "No theory of the causation of tumor growth can be satisfactory which does not apply equally to innocent and to malignant tumors. No hard and fast line of demarcation can be drawn between the innocent and the malignant representatives of many different types of tumor; that the same tumor may be at one time innocent, at another time malignant; and that the power of dessemination, instead of being limited to malignant tumors as was formerly supposed, is possessed also by many innocent tumors."

Ball notes the close analogy between the change of a cutaneous wart into a malignant epithelioma and the transformation of a long standing purely adenomatous growth into a cancer of the rectum. So long as the proliferation continues in an orderly manner and the growth is limited by a capsule or the basement membrane, we may speak of it as benign; when, however, the cells break through their limiting membrane and infiltrate adjacent tissues, growth is anarchic and the tumor is malignant.

In 1867, Waldeyer stated that all carcinomas were epithelial growths, originating from corresponding epithelium, and that the secondary deposits were derived from transplanted cells, to which Virchow assented. The marked resemblance of beginning malignant growth to inflamed tissue so impressed Waldeyer that a few years later he asked: "Is it possible that the excessive nourishment and loosening of the connective tissue thereby involved, assist in the advance of the epithelial cells? Is it not possible that in this way local chronic inflammatory processes, especially those arising from repeated irritation which cause circumscribed inflammation, may eventually pass over into cancerous degeneration?"

Thiersch, Cohnheim, Ribbert, and other investigators have proposed theories as to the causation of cancer.

Adami, Benecke, Marchand, von Hausemann, and others seek the cause of cancer in the changed biological properties of the cells, namely, differentiation, function, and growth or vegetation. They recognize the individual cell as the unit containing and disseminating the disease. The question with them is the nature of the influences at work which inhibit differentiation while permitting growth, or vegetation. Adami considers several agents responsible, *e.g.* senescent loss of function and chronic inflammation, either mechanical or microbic in nature.

Oertel conceives the chromatin of the nucleus as of two orders, one controlling growth, the other

FIG. 2—Adenocarcinoma of the rectum.

function. The latter may be lost while the cell still retains the power of proliferation. But these theories lead into the difficult field of biochemistry.

Finally experimental work in the transplantation of tumors in animals of the same and different species and the work of those who believe in the

parasitic causation of cancer have been pursued with great zeal. The evidence adduced, however, has been largely of a negative character and the true cause of cancer is still undiscovered.

A striking fact of common knowledge is that the cancer cell, when transferred through the blood or lymph stream, is capable of reproducing a neoplasm similar to the parent growth. For example, metastatic carcinoma of the liver, secondary to adenocarcinoma of the rectum, as Cripps says, "cannot only be identified as consisting of the columnar cells of the rectum, but they actually in the liver grow into a gland tissue identical with Lieberkühn's follicles of the rectum."

In a word, all that can be stated positively is that cancer begins as a small local process; that it excites no reaction in the blood whereby a diagnosis can be made; that the individual cancer cell is the parasite of cancer, and whatever eventually explains the origin of cancer will also explain the transformation of a benign into a malignant growth.

Malignant change in simple polyp is rare indeed, but I know of one instance in which the pathologist reported such transformation in the pedicle at its point of attachment to the mucosa. I have also to report the case of Mr. K., aged 76 years, referred

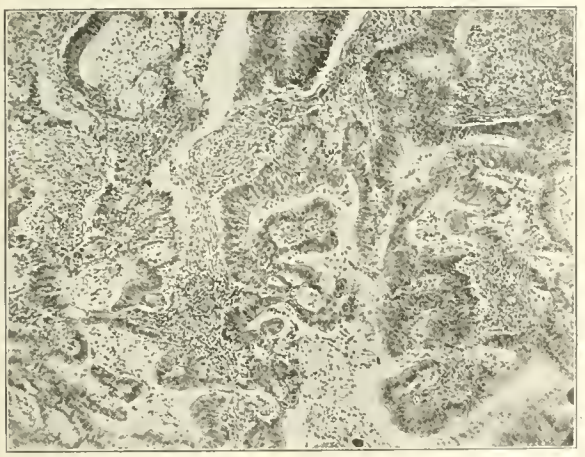

Fig. 3.—Transformation of an adenoma into an adenocarcinoma.

April 26, 1915, with a history of rectal bleeding of eight years' duration, progressive constipation, and a protrusion which at first occurred only at stool and could be reduced, but in recent years remained permanently outside and forced the patient to sit on one buttock. Examination showed a reniform tumor 3½ x 2 inches attached just within the anal verge of the left side and to both commissures for about two-thirds of the circumference of the canal. (Fig. 2.) On April 30, 1915, the tumor was removed under local anesthesia. Both the clinical and the histological diagnosis was adenocarcinoma. (Fig. 3.) This is a clear example of a simple adenoma which, as a result of repeated and prolonged trauma, became malignant. The lesson is that both single and multiple polypi or adenomata should be removed at the earliest possible moment after the diagnosis is made.

Villous tumor or adenoma differs in no way from a simple adenoma except in form and in its greater size. Histologically it is of the same structure. Its tendency to bleed may render it clinically malignant though microscopically benign. Allingham and others have reported cases as recurring in a malignant form after operation. Hence these growths should be extirpated early, thoroughly, and radically.

Multiple adenomata are the most important and serious type of benign growths of the intestine. Their usual site is the lower colon and rectum. They may, however, literally stud the mucosa of the entire colon, as in my case detailed above. At the 1909 meeting of this society, Tuttle reported eight cases of multiple adenomata, four of which in the hands of others and one in his own developed malignancy after local treatment by snaring, curettage, or cauterization; whereas in three children the growths were controlled by local flushing and snaring of the pedunculated forms. One of these children, irrigated through a cecostomy, developed recurrence five years later. Tuttle sagely asked: "May we not obtain better results by prolonged functional rest, especially when the growths are not well defined?"

Multiple adenomata, as such, may have a malignant effect as a result of the symptoms, diarrhea, hemorrhage, etc., to which they give rise, but the chief danger in their neglect or improper treatment is their liability to change into adenocarcinoma. In a large number of cases collected from the literature, more than 40 per cent. had undergone malignant transformation.

Treatment is palliative or operative. Palliative measures, as irrigation, suitable diet, tonics, etc., have kept the disease in abeyance for many years in certain cases—even some cures are reported.

Enterostomy above the growths prevents the feces from irritating the tumors. They shrink and sometimes disappear but the liability to recurrence is very great unless the enterostomy is maintained a long time after the disappearance of the growths.

Removal of the tumors singly by the snare or *en masse* by curettage or cauterization is very unsatisfactory, for, as pointed out, these measures are apt to be followed by a local malignant recurrence.

Radical extirpation of the portion of the colon involved is the ideal treatment. Practically the general condition of these patients precludes such radical measures at first for this would usually mean colectomy, partial or total. Lilienthal obtained a cure by operating in two stages, first ileosigmoidostomy and later colectomy. The curative, operative procedure indicated, then, is enterostomy, either in the colon above the growths, or in the terminal ileum when the entire colon is affected. If the tumors disappear, the enterostomy may be closed. If they persist, after prolonged trial of irrigations, and the patient's general condition warrants it, partial or total colectomy is indicated with implantation of the ileum low down into the sigmoid, the operation being performed either in one or preferably in two stages.

FRACTURE AND DISLOCATION OF THE PROXIMAL END OF THE FIRST METACARPAL BONE AND FRACTURE OF THE TRAPEZIUM.

By C. WINFIELD PERKINS, M.D.,

NEW YORK.

ASSISTANT SURGEON AND ROENTGENOLOGIST, CUMBERLAND ST. HOSPITAL, DEPARTMENT PUBLIC CHARITIES.

The comparative rarity of such injuries, the obscurity of the diagnostic signs, and the necessity of Roentgenological examination suggested to the au-

thor the possibility that these two cases might be of interest to the general profession.

Sprains, fractures, and dislocations at the base of the first metacarpal bone and the trapezium are frequently met with in athletes—in fact any form of violence sufficient to tear the ligament either of the carpal or the metacarpal phalangeal joint, associated with violence in the direction of the long axis of the bone, is sufficient to produce the injury. The symptoms are pain, effusion, and stiffness in the joint. If a fracture be present, it is exceedingly difficult to determine crepitas on account of the swelling and the diminutiveness of the injured bone. The necessity of distinguishing a sprain from a fracture of the base of the first metacarpal bone and trapezium becomes immediately apparent.

Fig. 1 shows a case of fracture and dislocation through the base of the proximal end of the metacarpal bone of the thumb. This type of fracture was first described by Bennett of Dublin and has received the name of Bennett's fracture. The general diagnostic signs of fracture were absent at the time of the injury, and the symptoms suggested more of a sprain or dislocation than a fracture. If the *x*-ray had not been available a positive diagnosis would have been impossible. The following is the history of the case:

Case I.—J. B. athlete, high pole vaulter, fell on the outstretched hand and thumb at the Princeton University sports in the Spring of 1908. At the time of the injury there were only the usual diagnostic signs of sprain, and no fracture at the time could be detected. Only after the usual methods for the treatment of sprain had failed to remove the cause I was consulted for a radiograph. The Roentgenogram shows a fracture at the proximal end of the first metacarpal bone of the thumb. Whitelocke of Oxford University reports a similar case in person of the University wicket keeper.

Fig. 1.—Fracture and dislocation at the base of the metacarpal bone—Bennett's fracture.

Case II.—Fig. 2 illustrates a fracture of the trapezium due to a fall on the outstretched thumb and hand. The usual symptoms were parallel to the above case, that of pain and swelling at the base of the thumb-joint, without deformity. The question as to the possibility of fracture immediately presented itself. The Roentgenographic examination cleared the diagnosis, showing a transverse fracture of the trapezium at the outer end of the bone.

Fig. 2.—Fracture of the outer end of the trapezium

The object of this article is to illustrate the close parallelism between the two cases in the objective symptoms and the method of receiving the injury. The positive diagnosis, however, rested absolutely on the Roentgenographic findings, these findings being necessary to clear away all doubt as to the condition. Strange as it may seem in this modern era of accurate diagnosis, there is still tendency to neglect the *x*-ray examination of so-called sprains. I trust this brief review will emphasize again the necessity of the Roentgenographic examination of every sprain; for the possibility of a hidden fracture must be always considered.

I desire to thank Dr. H. E. Wright of Princeton, N. J., for the courtesy of reviewing the first case. Case II is from the service of Dr. H. H. Schall, Cumberland Hospital D. P. C., New York City.

234 Central Park West.

REPORT OF 77 CASES OF ACUTE POLIOMYELITIS TREATED IN THE NEW YORK THROAT, NOSE AND LUNG HOSPITAL BY INTRASPINAL INJECTIONS OF ADRENALIN CHLORIDE.

By P. M. Lewis, M.D.,

New York.

House Surgeon, New York Throat, Nose and Lung Hospital; formerly Demonstrator of Physiology in the Atlanta Medical College, Emory University, Atlanta, Ga.

It may be asked why an eye, ear, nose and throat hospital has been treating cases of infantile paralysis; in July, when the epidemic was rapidly growing, the city hospitals were not able to take care of all of the cases, and the board of health made an appeal to the private and semi-private institu-

tions of the city to take and care for some of the little patients. This institution opened its doors to the service and has treated seventy-seven of the cases.

Symptoms.—The prodromal or preparalytic disturbances are varied, and may extend over a period of time varying from a few hours to six or eight days. In none of the cases did paralysis develop without some premonitory symptoms.

FIG. 1.—Left facial paralysis of 5 weeks' duration. For the first few days of the disease the patient had general paralysis with respiratory embarrassment. All the paralysis has cleared up except the facial

Fever is one of the most constant of the initial symptoms. It usually ranges from 100 to 105°, and is maintained from two to six days as a rule. There were noted a few cases where the temperature went above 106°. The fall in the temperature is most frequently rapid, as in crisis. In most cases the subsiding temperature not only reaches normal but oscillations from normal to a subnormal level continue for a few hours or a few days. A second rise in temperature is infrequent unless as a consequence of some complication. The height of the temperature offers no index as to the extent of the subsequent paralysis. Accompanying the temperature are other initial symptoms which, however, are present in numerous other conditions, but are more or less constant in poliomyelitis and should arouse suspicion on the part of the examiner. The patient presents a history of becoming very irritable, and this may be the first indication of illness noted by the relatives. With this indispisition and averseness is found acute tenderness, which may be diffiuse or localized. In a large percentage of the cases the pain and tenderness are localized over the spine and the extremity or extremities which will subsequently be involved in the paralytic stage. The patient often expresses anxiety and protest if an attempt is made to disturb it. There is a great restlessness in bed, the child turning from side to side and refusing to lie on the back, which is hyperextended.

Headache may or may not be present; vomiting or attempts at vomiting are infrequent as initial symptoms. Perspiration often appears and may be very copious. Rigidity of the neck is a very important symptom, and with this is usually found hyperextension, which is rather marked at times

FIG. 2.—Same as Fig. 1, during a feeble attempt at smiling.

and lasting up into the paralytic stage of the disease, constantly keeping the attendant looking for a probable meningitis. Great pain is experienced by the patient upon trying to bend the head forward. The spinal rigidity usually clears up by the time the temperature has abated.

Valuable information of the impending disease can be acquired by a careful study of the reflexes, both skin (superficial) and tendon. Reflex disturbances are noted during the preparalytic stage and last for varying lengths of time, depending upon the severity of the paresis, but there is a marked predisposition toward the return of the reflexes.

The skin reflexes are more important in infants, as it is often difficult to determine the integrity of the tendon reflexes in these patients. They are readily elicited when present and their absence is easily affirmed. Absence of the plantar and cremasteric reflexes, the ones most frequently perverted, indicates some disturbance of the reflex arc between the second and third sacral and the first and second lumbar segments of the spinal cord, respectively. In one case were found the right plantar and the left cremasteric reflexes absent, while the left plantar and the right cremasteric were normal. Some cases, however, where the testes have not descended into the scrotum, would eliminate the testing for the cremasteric phenomenon. This was true in two children between the ages of 2 and 3 years. Absence of the abdominal, epigastric, and scapular reflexes which occurs in the majority of cases, is conspicuously determined. Both abdominal and epigastric may be absent in the same individual, or either one of them may be absent with the others intact.

One case exhibited an increase in the knee jerk on the right side and an absence on the left side,

with a beginning paralysis in both legs. After a day's progress of the paralysis the right knee jerk disappeared. Another was one of general paralysis, slight bulbar involvement and an increase in both patellar and tendon reflexes. Still another patient, in which there was a partial paralysis of the right arm only, showed an absence of the scapular reflex and the right elbow tendon reflex, with an increase in both knee jerks. The paralysis in this case cleared up in a few days, accompanied by a return to normal of all the reflexes.

Various skin eruptions are frequently found and may occur during any stage of the disease, but are more prominent in the first few days. The rash is transient, rarely lasting over a few hours, and occurs on any or all parts of the body. However, the face and chest are the parts more frequently affected. Quite interesting were two cases, in a brother and sister, 3 and 2 years of age, respectively, who were admitted with very severe impetigo contagiosa and paralytic involvement also. The impetigo lesions were to be found on all parts of the body; in fact the disease was so marked that attention was directed more toward its treatment than to that of the paralysis. The impetigo responded rapidly to the application of ammoniated mercury, and within two weeks was completely cleared up.

The preparalytic stage may show various respiratory symptoms. Bronchopneumonia was present in one case. Bronchitis is frequently found. Only a very few cases showed any inflammation of the tonsils. This is contrary to the findings of other men, for a majority of the writers on the subject have reported tonsillar involvement in most cases. More frequent than tonsillitis are pharyngitis and laryngitis, usually occurring simultaneously with some inflammation of the nasal mucous membrance. Conjunctivitis was often present. It has been infrequent to obtain a positive history of gastrointestinal disturbances prior to admission in the hospital. There have been a few cases of persistent constipation, in both the preparalytic and paralytic stages. Flatulence is a more frequent disturbance than either constipation or diarrhea, and is found in both stages of the disease.

It is usually ascertained, both subjectively and objectively, that there is an existing weakness in all the muscles that will subsequently be paralyzed. This phenomenon is sometimes noticed several days before the actual paralysis appears. As will be described later, this may be the only motor disturbance in the abortive cases.

Paralytic Stage. Many of the initial symptoms continue uninterrupted into the paralytic stage. The fever is always present when the paralysis appears and usually subsides within a few days unless kept up by some complication. The motor disturbances are found to occur some time during the first two or three days. As was previously stated, the first impairment in motion, noticed by the patient or relatives, is an existing weakness. The muscles are easily fatigued. Active movements soon disappear and the affected limbs become passive if the paralysis is complete or nearly so. The patient no longer moves the involved extremity. If the paresis is partial the motion is conspicuously limited. In case of affected legs, standing is impossible. If only one leg is involved the patient may be able to stand on the sound one. When attempts are made to stand on an affected limb, the marked hypotonicity of the leg muscles allows extensive hyperextension at the knee.

It is frequently observed that before the paresis has made much progress there is a decided diminution in the resistance offered to passive motion. This fact is of special consequence in the case of infants, for it is often difficult to determine whether or not there is any loss of active motion in these little patients. In the most severe cases it is rare to find complete paralysis of all the limb muscles, for there usually remains, if but slight, the power either to flex or to extend the toes or fingers, as the case may be. The reflex anomalies are found during the paralytic stage of the disease, but they usually precede the paralysis. There is marked hypotonicity of the affected muscles. This is noted by the flaccidity to touch and the abnormally slight resistance offered to passive movements. The hypotonicity is sometimes not only found in the paralyzed

Fig. 3.—Girl 9 years old with marked atrophic changes in the muscles of all the extremities after 7 weeks' duration of the disease. There is also a talipes equinovarus present in both feet.

muscles, but even the unaffected muscles may show loss of tone. In the cases of general paralysis, when the patient is lifted out of bed the head and extremities fall about as if in a lifeless state.

Inside of two or three weeks as the disease progresses, it is noticeable in connection with the motor disturbances and the hypotonicity, that trophic changes are beginning to take place in the paralyzed muscles. The atrophy progresses rapidly and may reach an extreme degree within a few weeks. The atrophic changes are due to the trophic disturbances and disuse. (See Fig. 3.)

The skin over the paralyzed muscles soon becomes extremely dry and adherent to the underlying connective tissue, and when one tries to pinch up the skin it cannot be separated from the underlying tissues as in health, but the whole mass is brought

up together. All reports state that bed-sores are never found. One patient, however, came in with a very bad bed-sore over the left gluteal region; this patient had been in bed with the disease for about three weeks. The temperature of the limb is very much lowered, there frequently being two or three degrees difference between the sound and paralyzed limb.

Incontinence of urine and feces is rare, except in the extreme cases approaching death. In some few cases retention of urine occurs. The longest time of retention in any case was fourteen hours. Catheterization was not necessary in any of them. The circulation in the affected limbs is greatly disturbed, the capillary circulation being sluggish, giving rise to a dusky purplish hue of the skin. Very frequently the surface has a mottled appearance.

The paralysis generally develops rapidly. The following table will show the distribution of the paralysis: Paralysis of one or both legs, 34 cases; Paralysis of one or both arms, 6 cases; Combined paralysis of leg and arm, 10 cases; General paralysis, 8 cases; Facial paralysis (see Figs. 1 and 2), 3 cases; Combined paralysis of leg and trunk, 8 cases; Laryngeal paralysis, 1 case; Abortive cases, 7.

The extensor muscles are by far the most frequently affected.

A few rare anomalies are sometimes seen. Spastic hemiplegia was found in one case. The sense of pain was absent in the same patient for about two weeks after the onset of the paralysis. The patient was a girl four years old and she did not complain of any pain when lumbar punctures were made to give the intraspinal injections of adrenalin. After about two weeks the sense of pain gradually returned to normal. In one case, for about thirty-six hours before death, there existed a paralytic diverging strabismus of both eyes. I have just learned that a physicion friend of mine has a little boy 4 years old with paralysis of the upper and lower extremities, and a few days ago there developed a converging strabismus of both eyes, but the condition is gradually clearing up. One patient 8 months old developed typical Cheyne-Stokes respirations, which lasted for about twelve hours before death ensued. The spleen seemed to be enlarged in a few cases.

Certain deformities of the feet occur in some cases where there is marked paralysis in the lower extremities. These conditions are minimized to a great extent by putting the feet up in plaster casts, but even then there will be found deformities in some cases. A few cases were admitted to the hospital with deformities, after having remained at home several days without the proper treatment. The feet anomalies observed are as follows: Equinus, 10; valgus, 2; varus, 5; equinvarus, 6; equinovalgus, 2. Contraction of the planta fascia is found in most all the cases with equinovarus.

The following case was unique from the involvement of the laryngeal muscles and the complications which later occurred, causing death as we were contemplating dismissing the case:

Female, aged 17 years; admitted to the hospital July 29, 1916. Gave a history of having had an organic heart lesion for eight years as diagnosed by several physicians. Six days previous to admission she became very hoarse with no other noticeable symptoms of any disturbance except headache; on the night of July 28, she complained of some spinal pain and later found that the left leg and arm had suddenly become paralyzed, and she was admitted with complete paralysis of those two extremities. There was also a complete wrist-drop on the left side. Other than the foregoing there were no alarming paralytic symptoms with the exeception that the laryngeal muscles seemed to be involved and patient talked only with difficulty and then just above a whisper. Examination showed that there was a paralysis of the left thyroarytenoid muscle and during the act of phonation the vocal band on the left side did not approximate the median line as did that of its fellow and as a consequence the rima vocalis was not reduced to its minimum size and the speech was impaired. Sections would have shown some inflammatory lesion at the origin of the left inferior laryngeal nerve whose fibers arise in connection with the spinal accessory.

The patient was given the routine treatment, improved rapidly and was walking in a few days, the wrist-drop having cleared up and the voice slightly better. The patient did have a slight mitral regurgitation which was only heard in the mid axillary line.

On Aug. 21, about 6 P. M., patient began complaining of difficulty in breathing and had to sit up so as to avoid the extreme suffocating feeling which came on if lying down. At this time examination showed the heart beating at the rate of 140 per minute with a marked mitral regurgitation; respirations 31 per minute, and no lung lesions. At 11 P. M. patient had not been able to lie in bed at all and was kept in a chair in as comfortable position as possible; all the valves of the heart were leaking; pulse 160; blood pressure very low; respirations more laborious and there were to be heard piping and bubbling râles all over the chest. She complained of severe abdominal pains and it was found that the abdomen was greatly distended by the presence of fluid in the abdominal cavity. The ascites had developed within an hour and a half. At 11.30 P. M. she vomited the copious meal which she had eaten at 5 P. M. when she was feeling normal. The heart and lung condition grew rapidly worse. I made a puncture into the pleural cavity and drew off 40 c.c. of turbid fluid; oxygen was administered under pressure by the Meltzer apparatus.

The oxygen gave great relief while it was being administered, but I saw it was only prolonging life by mechanical means and discontinued it. The patient died at 1 A. M. She could move all the extremities freely, held the head up and was perfectly conscious, talking all the time to within a minute and a half before death came. Immediately after death I lowered the head and drained off several ounces of hemorrhagic fluid from the lungs.

The immediate cause of death was a failure of compensation in the organic heart lesion and edema of the lungs. It is probable that the inflammatory area in the neighborhood of the left inferior laryngeal nerve revived and spread to the origin of the vagus and the heart was affected as a consequence.

Spinal Fluid. Due to the fact that we have not yet got a systematic report on all of the spinal fluid examinations, I shall not relate any of the data other than say that the most characteristic feature of the fluid examinations was the positive Noguchi reaction. Usually the spinal fluid is under an increased pressure in these cases, several cubic centimeters being removed at times. (P. M. Lewis. MEDICAL RECORD, July 29, 1916.) From one case 30 c. c. of fluid were removed at three different times, and from 15 to 25 c. c. were removed from several patients. The fluid was mostly clear when removed from the spinal canal; in some few cases it was opalescent. In only one case was there found a true hemorrhagic fluid, and it was a case where meningitis caused by the Friedlander bacillus complicated the poliomyelitis.

Complications are not very infrequent in this malady. The following complications were encountered in the cases under our care in the hospital: Measles, two cases; one of these developed early in the disease and was probably contracted before the poliomyelitis. Whooping cough developed in four cases after from three to six weeks' duration. Meningitis complicated two cases, one of which was caused by the Friedlander bacillus. Cultures of the organism were made from specimens of the spinal

fluid and the blood. The patient died after about eight days' duration. The etiology of the other case was never determined. The prognosis was very grave, but there was complete recovery in about ten days. Various rashes sometimes occur on different parts of the body. As would naturally be expected, there were marked gastrointestinal and nutritional disturbances in most of the little infants who had previously been breast-fed.

Abortive Cases. Of the seventy-seven cases seven of them were diagnosed as abortive cases. There are no signs or symptoms that will differentiate the abortive form of the disease from that of the true paralytic type during the initial stage, and not until paralytic disturbances occur can you tell whether or not the case will be abortive. There may be found all the initial symptoms that accompany the typical paralytic cases, *e.g.* fever, malaise, headache, pain in various parts of the body, spinal rigidity, and as was previously mentioned, there may be a distinct weakness to be found in various muscles. Instead of the condition progressing with an ensuing paralysis all the symptoms clear up and the patient is again normal. These patients were given the routine intraspinal injections of adrenalin until they proved to be abortive cases.

Prognosis. The figures and data that are given below could have no special importance when taken alone, for we have had only seventy-seven cases, as compared to the several thousand cases in various other hospitals. The essentials to be shown regard the mortality and the morbidity in these cases after treatment by intraspinal injections of adrenalin. Conclusions favorable to the adrenalin treatment can be reached by comparing the results with the results of others where adrenalin was not used. This is more satisfactory, since they are cases of the same epidemic and in the same locality. The following figures show that the mortality varies in different epidemics E. Austria, 1908, 22.5 per cent; N. Austria, 1908, 10.8 per cent; Germany, 1909. (Arnesberg), 12.3 per cent; Sweden, 1905, 16.7 per cent; Syria, 1908, 13.16 per cent; Norway, 1905. 14.56 per cent; Germany, 1909 (Hanover), 20.55 per cent.

Up to the present writing the mortality in the city of New York has been 23.9 per cent. It is hardly fair to include the deaths that occur after the first twelve or fifteen days of the disease, for if death occurs later than this it is usually due to some complication. Considering this, the mortality percentage due entirely to poliomyelitis would probably be decreased. Nor is it doing justice to the adrenalin treatment to include the mortalities that occurred within a short time after admission to the hospital, some of them not getting any and others only a few injections of adrenalin.

We may summarize the fatalities occurring in the seventy-seven cases, which form the basis of our study, in the accompanying table.

We would conclude, therefore, that out of the eighteen deaths only five children (6.49 per cent) died from poliomyelitis under the adrenalin treatment. The decision of all fair-minded critics will harmonize with the above figures.

The correct statistics as to the morbidity in these cases cannot be compiled until the end of from six to twelve months, for cases have been shown to recover several months after the onset of the disease. Of the fifty-nine cases surviving, the prognosis as to complete recovery is exceedingly gratifying.

	Deaths.	Per Cent.
Number of deaths that occurred between 5 and 20 hours after admission, in moribund cases	3	3.89
Number of deaths that occurred between 20 and 46 hours after admission, in moribund cases	3	3.89
Number of deaths occurring after the third day in the cases admitted in a moribund condition, but having had a fair chance under the adrenalin treatment	5	6.49
Number of deaths occurring in infants from gastro-intestinal and nutritional disturbances (having been previously breast fed) between 20 and 49 days after admission with complete or partial recovery from poliomyelitis	5	6.49
Number of deaths occurring on the 24th day after admission from an organic heart lesion (recovery from paralysis except in the case of some of the laryngeal muscles) probably aggravated by the poliomyelitis	1	1.29
Number of deaths occurring on the 15th day from cerebrospinal meningitis	1	1.29

In the epidemic in New York in 1907, in only 5.3 per cent a complete, and 1.8 per cent almost complete disappearance of the paralysis occurred.

The following table briefly outlines the condition of the fifty-nine case after six to ten weeks' duration from the onset of the disease:

	No. of Cases	Per Cent.
Complete recovery	21	35.57
Greatly improved with all indications that complete recovery will soon follow	21	35.57
Probably permanent disability in one or more groups of muscles	17	28.79
Total	59	

Of the twenty-one cases in which there was complete recovery four of them were admitted in an extremely moribund condition, and little or no hope was entertained as to their surviving. Their recovery may or may not be attributed to the action of adrenalin. The fact that it did them no harm has been well demonstrated.

Treatment. In searching medical literature for some remedial measure to be used in the treatment of acute poliomyelitis, about the only information found was this: No specific therapy is yet available and the treatment must be purely symptomatic. Facing this predicament on one hand, the numerous little innocent victims of the disease on the other, we would naturally use any rational measure suggested.

On the first day that we received any of the paralytic cases, Dr. S. J. Meltzer of the Rockefeller Institute, after having reached certain experimental results (S. J. Meltzer, MEDICAL RECORD, July 22, 1916) advised the intraspinal injections of adrenalin.

The remedy has been given a fair trial in our cases and its use is highly recommended.

The 1-1000 solution of adrenalin contains 0.5 per cent of chloretone. In order to get rid of this, a bottle of adrenalin, with the cork removed, was placed in a bath of boiling water for two or three minutes. The solution was then allowed to cool and the injections were made without diluting the adrenalin with anything. A fresh preparation of the drug was used each time.

In order to increase the space between the interspinous processes, a bottle 6 in. in diameter with a small pillow on it was placed on the table and the patient flexed across the contrivance. The skin over the area where the puncture was to be made was painted with tincture of iodine, normal strength,

and a moist dressing of saturated boric solution placed on after the injection. This procedure controlled the infection wonderfully well. As a result of the frequent punctures, most cases had a bit of traumatic exudate collecting under the skin, but only a very small percentage showed even the slightest signs of infection. A medium-sized, stout aspirating needle is best used, for a small flexible needle is hard to control and takes to the bone easily.

The punctures are best made between the fourth and fifth lumbar vertebræ. It is not wise to give more than one injection through the same skin puncture for fear of carrying infection into the spinal canal. If infection occurs it is always superficial. The skin can be moved over a limited radius, so it was pulled down, up, or to the side at will and new punctures made in order to miss the infection. If the traumatic exudate occurring under the skin tends to prevent the location of the spinous processes of the fourth and fifth lumbar vertebræ, the puncture can be made higher up or lower down. This was frequently done and as the wounds began to heal sufficiently the punctures could be made over the same area again. The individual skilled in making spinal punctures can always tell the moment his needle has reached the spinal canal and he can go as high up as the first and second lumbar interspaces without fear of doing damage to the cord.

Intraspinal pressure, if it was present, was always relieved and then 2 c. c. of adrenalin (1-1000 sol.) injected. The injections were given every six hours, day and night, until the temperature had remained normal for forty-eight hours unless kept up by something other than the poliomyelitis.

In the cases with respiratory involvement it is best to give the injections with the patients in the lateral prone position, for to put them face down embarrasses the respirations and marked cyanosis follows. If this does occur the condition can be cleared up by the administration of oxygen.

A local anesthetic was not used before the injections, for it would produce about as much pain in its administration as making the puncture.

By giving the adrenalin one clears the way for three very important measures, viz., one relieves any intraspinal pressure that may be present; the fluid can be collected for examinations, and adrenalin, the most valuable therapeutic remedy yet used in these cases, is given.

Urotropin was given in moderate doses during the acute stage of the disease. As soon as a tendency toward deformity was noticed in any extremity it was put up in plaster casts.

It being the hottest time of the year when the cases were brought in, it was exceedingly difficult, in the case of the little infants which had previously been breast-fed, to keep them in a normal state of nutrition.

233 East Fifty-seventh Street.

Adrenalin in the Treatment of Anaphylaxis.—Parhon and Buzgan have believed for a long time that adrenalin was indicated in anaphylaxis because in part of the hypotension present in anaphylactic shock. In a severe case of the latter following a cholera immunization, with cold extremities, extinction of voice, dilatation of pupils and other severe symptoms the body was surrounded by hot-water bottles and ether and caffeine injected. It was then adrenalin was first tested, fifteen minutes after the onset of the symptoms. Within five minutes the symptoms of shock had quite vanished. In two subsequent cases adrenalin was the sole remedy used and the results were the same.—*Comptes rendus de la Société de Biologie.*

REFLECTIONS ON POLIOMYELITIS.

By D. W. WYNKOOP, M.D.,

HEALTH OFFICER, BABYLON, N. Y.

It may be of interest to the profession to have a statistical report of twenty-four actual cases of anterior poliomyelitis that have come under my observation as Health Officer of the Village of Babylon, N. Y., during the month of August, 1916. When I say "actual" I am excluding all cases where there was doubt and only accepting those where the puncture diagnosis was made by the State Board of Health.

The average age was 5½ years; extremes, 16 years and 1 year. The average lapse of time from onset of the disease to examination and diagnostic puncture was three days; extremes 7 days and 1 day. The number of cases showing paralytic symptoms was 8 out of 24. The number of deaths was 1 out of 24 cases. There was partial or complete recovery from paralysis during the first month in 7 out of 8 cases.

Situation of paralysis: Both legs, 30 per cent; both feet, 10 per cent; right arm, 10 per cent; right leg, 10 per cent; deltoid, 20 per cent; lumbar muscles, 10 per cent; cervical and respiratory muscles, 10 per cent. (These last cases are usually fatal.)

Symptom of coryza or discharge of nose and throat were conspicuously marked by their absence in most of the cases I examined. This does not support the contention as to the probable source of infection.

Prodromal symptoms: Strawberry tongue, 90 per cent; fever, 100 per cent; pain in head, 90 per cent; stiff neck, 80 per cent; vomiting, 75 per cent; drowsiness, 80 per cent; pain in back, 40 per cent; gastroenteritis, 25 per cent; irritability, 30 per cent; conjunctivitis, 40 per cent.

(I have noticed the last symptom to persist for one and two weeks after the onset of the disease. It is in a mild form and may only be indicated offhand by the patient rubbing its eye frequently.)

The average time from the first symptom of illness to paralytic manifestation was one week. The most rapid case, ending fatally, apparently ran its course in forty-eight hours from the onset.

The average number of lymphocytes found in microscopic field was 233; the highest count showed 690; in this case there was no paralysis following; the lowest count showed twelve lymphocytes. A week following puncture in this case the child came down with a paralysis of both legs. That the count of lymph cells was not greater can be attributed to early puncture (day of onset). Had puncture been made four or five days later we would have undoubtedly found a larger count.

Therapeutic value of puncture. In 80 per cent of the cases where there was a marked increase of pressure of the spinal fluid, pain in the neck and headache ceased altogether or were greatly improved immediately following the operation of lumbar puncture. Where pressure was slight there was no noticeable improvement. Cases of paralysis in which no lumbar puncture was made were more severe than those occurring after puncture was performed. This latter may be accounted for, however, by the fact that the earlier cases of the epidemic seemed more severe than the more recent ones. Personally I am inclined to the belief that puncture is a distinct mechanical aid in relief of the disease through diminution of intraspinal pressure. Puncture is of no use after symptoms of paralysis have set in.

Puncture is of no diagnostic value after the tenth

day from onset. From this time on the microscopic examination will prove negative even with paralytic symptoms present.

Operation of Puncture. It is best in every instance to have the State Board of Health perform the operation. In a good many cases where the disease has run a light course the parents will begin to express a doubt that the little one was ever stricken. An unofficial surgeon without verified records will have some little difficulty in satisfying the family or a jury as to what he found under the microscope.

The sudden withdrawing of too much fluid when under high pressure may produce unfavorable symptoms (probably due to temporary hernia of the pons). The risk of this can be avoided by inserting the trochar back into the needle occasionally so that the flow shall not be continuous.

A second puncture made on following day, in doubtful cases, is apt to prove unsatisfactory, it being often difficult to obtain sufficient fluid to make a proper examination. It is better to allow two or three days to elapse between punctures. The use of cocaine in young children before inserting the spinal needle seems useless. They make just as much trouble over the hypodermic needle as the other. In children over eight years cocainizing the parts is advisable. An experienced person in holding a child greatly facilitates the operation. It is advisable not to have any of the members of the family present when the operation is performed. If the periosteum is scraped by the needle (it frequently happens) considerable indefinite pain is experienced. I have seen no ill effects following puncture.

Postparalytic pains occur in 100 per cent of the cases and are exceeding intense for the first week. The onset of the pain gives the sensation that the skin is being pricked by pins in the portion paralyzed. This pain is not well controlled by opiates and for the general condition they should be avoided. Massage of any kind is also contraindicated in this acute stage. The simpler analgesics and enveloping the paralyzed parts in cotton will probably prove the most effective. Except where paralysis has been very extensive the pains completely subside after one week from the onset of the paralysis.

The administration of drugs in an attempt at cure can be considered as a waste of time and in some cases most harmful. In particular I refer to urotropin in large continued doses. I have seen an acute bloody nephritis and cystitis following which was most painful. There were two doubtful cases in my series. In one it was necessary to exclude a possible diagnosis of epileptic hysteria. The other case was one in which a tertiary syphilitic condition of the meninges near the base of the brain was present. In both these cases, spinal puncture showed a low count, but the general symptoms were of an intense poliomyelitic character.

The theory of contagion is one that I should hesitate to accept without reservation. That the disease is highly infectious there can be no doubt. That it is selective to a high degree is also self evident. In one family of ten children, all under sixteen years of age, only one child developed the disease. This one was susceptible and the balance were immune.

I believe that a six weeks quarantine is unnecessarily harsh and does not accomplish much towards stamping out the disease. The fear of this rigid quarantine tempts the family to hide the presence of the disease. Were I asked what I considered the best means of stopping an epidemic, without qualification I should suggest the adoption by all families and doctors of the following rule:—"If a child is ill for twenty-four hours and household remedies, such as castor oil or calomel, have failed to ameliorate the condition, the family doctor should be called at once. If in turn the doctor is unable to make a positive diagnosis within twenty-four hours let him ask the State diagnostician to make a lumbar puncture. If this were done in every case we would soon get hold of the ambulatory ones who are only sick for a few days and are true carriers of the infection.

If the quarantine by the State is going to work unnecessary hardship to the family it will be impossible for the three elements (family, doctor, and State diagnostician) to work in harmony. I believe that a child who has this disease is only a carrier during the acute stage and that a three weeks quarantine is all that should be demanded. I think it extremely doubtful that a healthy adult or healthy child can be the carrier of the disease. These are all, however, individual opinions and as such can be considered for what they are worth.

THE CLINICAL DELIMITATION OF HYSTERIA.

By MEYER SOLOMON, M.D.,

CHICAGO.

In the New York Medical Journal for November 6, 1915, appeared a previous paper on this subject by the writer in which it was pointed out, as is so well known to all, that the term hysteria, like so many other terms in medicine, has been so generally abused by specialists in nervous and mental diseases as well as by the average physician, that nowadays one hardly knows what a particular physician means when he employs this term as a clinical diagnosis. And this in spite of the acknowledged fact that dismemberment of the hysteria concept of other days has been proceeding in progressive fashion in recent years. I need not here repeat the brief discussion which was entered into in the first paper when considering the clinical concepts of hysteria maintained by others, particularly by Babinski and by Dejerine and Gauckler.

It may be stated as a general proposition that in most cases, even in the writings of neurologists and psychiatrists, the term hysteria is by no means used with that definiteness which scientific medicine really demands. In truth, since there are a number of different clinical concepts of hysteria, it is impossible for the reader to know in what sense this term is being used by a writer, unless an explanatory note or apologia is added. No matter in what sense this name be applied, it is none the less true that from the etymological and scientific standpoint it is entirely out of place and actually has no meaning to fit into the clinical concepts of hysteria, be they what they may. It is an etiological diagnosis of the days gone by when the uterus was supposed to be the basic factor in the causation of the symptomatologic pictures classified under this disease-heading. Aside from the Freudian school, which, unwarrantedly and without proof, in fact, in spite of a mass of proof to the contrary, still attributes this disease to a so-called sexual etiology, the mass of physicians, specialists in neurology and psychiatry and the rest, generally agree that the insistence on such a one-sided and exclusive causative agent is baseless and contrary to fact and observation. Nevertheless, it is questionable whether this word, as a clinical diagnosis, can be dislodged from its

prominent place at this time, even if our wishes be limited to the specialists in this field. Moreover, until another more desirable and generally acceptable term is proposed or gains currency, it is necessary to adhere to this term, provided it be given some definite, clean-cut and undeniable clinical meaning, so that it will represent a clinical concept or syndrome which can be called to mind immediately and which will stand in our minds for such a manifest cut-off group of symptoms that we can impart our concept to another without annoying preliminary and circuitous explanation and elaboration. In the previous paper on this subject I endeavored to present such a clinical concept of this disease. The gist of it may be here repeated.

I advocated the limitation of the term hysteria to the gross sensorimotor, including the special sense disturbances which are the bodily affects of a lasting nature, flowing out of emotional upset; the pure or true crises being included in this picture.

In true or pure hysteria we may agree with Dejerine and Gauckler that a state of relative indifference or passivity with respect to the physical condition be required as the typical mental state accompanying the somatic picture. Where psychic states of another kind are present, an appropriate name, in accordance with present or current psychopathological or psychiatric nomenclature or otherwise, may be added as a diagnosis, to complete the clinical picture.

In other words I would speak (1) of true, pure, genuine, uncomplicated, typical hysteria (presenting the phenomena mentioned in this paper, and consisting sometically of functional or psychogenetic or emotogenetic disorders of the voluntary nervous system, and psychologically of a mental state of relative passivity or indifference); and (2) of false, complicated, atypical hysteria (presenting the somatic phenomena but a different or superadded mental state). The second group would thus include such complex syndromes as are found in dementia precox, where pronounced somatic phenomena are so frequently present in addition to the more frank mental states of protean nature.

It is thus seen that it is the somatic manifestations which are here considered as the real indication or stamp mark of what we have agreed to call by the old name, hysteria. And since the dividing line must be drawn somewhere between the associated mental states, I would provisionally agree with Dejerine and Gauckler and require an associated mental state of relative passivity or indifference for what we may call the pure, typical cases, while the mental states found present in what are called in this communication the atypical cases should receive their appropriate names.

In the physical sphere the following conditions should be carefully excluded from the syndrome or disease-picture which I have mentioned as being reserved for socalled hysteria: organic disease of the peripheral or other parts of the body, including the nervous system; syndromes belonging under the nosological label of the other psychoneurotic or psychotic (minor or major) states; simulation, deceit, and deception; Babinski's pithiatism (which includes symptoms due to suggestion and curable by mere suggestion-persuasion); Babinski's emotive (including for the most part the visceral manifestions of emotional origin and of a functional nature) and reflex phenomena (the reflex manifestations consisting, for example, of pilomotor, sweat gland, and other cutaneous phenomena of this type).

Dismembering the hysteria of old in this manner we find that there remains as the ear-mark of hysteria the group of symptoms above given: namely, the *sensorimotor disturbances, including the disturbances of the special senses, and the pure major attacks*, these not being due to suggestion or simulation, but being of the nature of protracted symptoms not removable by the suggestion-persuasion of Babinski.

In brief, we find that hysteria is here limited to functional disturbances of the voluntary nervous system, produced by emotion, and not due to mere suggestion or the like. The other features mentioned hitherto may complicate the picture, but the additional diagnosis necessary to a full understanding of the picture would make things so much clearer and more scientific. For instance, there may be true hysteria, complicated by simulation or deceit and deception, or by organic disease, or by by an anxiety state, or by some other somatic or psychic syndrome. But the presence of true hysteria, as given in this paper, would not be confused with these other conditions, and the term hysteria would not be employed to include these other conditions, but they would each be separately named. None of these other groups is characteristic of all hysterics, but their occurrence varies with the makeup of the individual in the particular case we may have under consideration and with the special circumstances there existing.

In this connection I may refer to the classification of diseases of the nervous system adopted by Jelliffe,[1] White,[2] and both of them together.[3] The division of the phenomena of diseases of the nervous system into those of the vegetative or involuntary nervous system, those of the sensorimotor or voluntary nervous system, and those of the purely psychical sphere harmonizes quite well with the viewpoint adopted in this paper. Considering this classification in relation to the functional disorders of the nervous system, as a result of emotion, hysteria would correspond to the middle group—functional sensorimotor syndromes, due to disorder of the voluntary nervous system, while functional disorders of the other two groups (the vegetative or involuntary nervous system and purely psychic manifestations) would be excluded from it.

In a paper on "Physiological Considerations in the Differential Diagnosis of Neurasthenic, Hysterical, and Psychotic Symptoms," I find that Donald Gregg[4] assumes the same standpoint.

Does not this give one a clinical concept of hysteria which is recalled without effort and of a far more definite nature than can be had from most previous clinical concepts of this disease? One can adopt this clinical concept without in any way committing one's self as to the exact nature of hysteria. And, to be frank, one can do away entirely with the word or name hysteria, and, without lessening the definiteness of our diagnosis, call this group of symptoms by its full name—*functional or psychogenetic disorders of the voluntary nervous system.*

A FATALITY FOLLOWING ACUTE OTITIS.

By IRVING WILSON VOORHEES, M.S., M.D.,

NEW YORK.

In January, 1916, the writer was consulted by a well-to-do gentleman from a Western city regarding pain and discharge in the right ear. Some three or four weeks previously he had passed through a fairly mild attack of grip (respiratory type) which had kept him in bed for a few days only. At the time I saw him he had come East for the Christmas holidays, and had been able to enjoy the festivities with friends in a suburb of New York city.

There had been considerable discharge of mucopus from the nose and a persistent cough brought the same kind of material from the chest. Appetite was fair, bowels regular, and general health good in a man of forty-one who had been always well. There had been no previous aural disease of any kind.

Two days preceding my examination the patient experienced severe pain in the right ear which lasted for three or four hours, followed by discharge. This pain had then practically disappeared, but a sensation of fullness remained. He complained of deafness, slight noises, and moderate discharge.

Examination of the nose showed swelling of the mucosa and a small amount of viscid yellowish discharge in the middle meati. The nasopharynx was red and swollen, yet the tubal orifices could be distinctly seen. The larynx was normal, but the tracheal mucous membrane was red, swollen, and plastered here and there with exudate. The left ear was normal in all respects. The right drum was red and somewhat swollen, but the chief landmarks were still present. There was a perforation in the antero-inferior quadrant through which a small amount of thin discharge was pulsating on its way outward. There was no mastoid tenderness.

The usual expectant treatment was instituted and the patient was advised to return in forty-eight hours. This he did not do, however, and I did not see him until the fifth day following. He then came to my office and a thorough examination was carried out, including tuning fork tests, etc. The condition was much the same in every respect. There was no pain or discomfort.

The patient sailed for Bermuda on the day following and no more was heard from him until two weeks later when the writer was summoned by cable to "come and do a mastoid at once." Within six hours I was aboard the steamer fully prepared for any complication that might be encountered. Fifty-two hours later I entered the hotel and was informed that the patient had died eight hours after my departure.

Going over the history the following was gleaned: The voyage was marred by rough weather, constant rain and cold (it was the middle of January). The patient "caught cold" and when he arrived consulted a doctor. His ear was inspected, but nothing was related of its condition. At this time there was pain, but not much discharge. Symptoms in nose, throat, and chest were marked. The physician stopped the treatment outlined in New York and gave the patient a nose wash to be snuffed up "out of the hand." The ear was to be syringed with a solution of peroxide every two hours.

From this time on the patient did poorly. He suffered much from right-sided headache and complained of general malaise. The daily temperature range averaged 101° F., mounting a little higher as time wore on. The patient, a graduate of Harvard and a highly intellectual man, kept a secret daily record of his condition, which in the light of subsequent facts proved of great interest. He tried to conceal his symptoms from his wife, because this was "a second honeymoon" and they had planned to remain on the island for three months. Nevertheless, headache, high temperature, and weakness continued until he was driven to bed with a nurse in constant attendance. As yet no definite diagnosis had been made, so at the insistence of the patient's wife a surgeon was brought in from one of the great British cruisers lying in the harbor. At this time the temperature was 104° F., the unilateral headache was intense, there was beginning paralysis of the right external rectus, and the surgeon looked upon the case as one of extreme gravity. After much effort an ambulance was secured and the unfortunate man was hauled some two miles to a hospital. While shaving the head preparatory to operation the patient suddenly died. The nurse tells me that respiration stopped and could not be again started, but the heart continued beating for some minutes. Temperature at this time was 106°. No autopsy was performed. The consensus of diagnostic opinion was: Mastoiditis, brain abscess, rupture into the lateral ventricle of the brain.

I publish this clinical note because the case bears a tragic significance from which we may draw profitable conclusions:

1. Any apparently "simple" acute otitis media is capable of producing dire results.

2. The appearance of the drum may be very misleading. Behind it may be lurking the deadly streptococcus mucosus.

3. A culture should be taken in every case and the predominant germ identified if possible.

4. Any abrupt cessation of discharge accompanied by severe unilateral headache is an unfailing sign of some complication calling for operation.

5. No patient with an acute otitis should be allowed to get away from the watchful eye of a trained otologist until all symptoms have disappeared and a condition of restitutio ad integum has been obtained.

14 Central Park West.

Favorable Action of Hypertonic Solutions and Mineral Oil in the Treatment of Infected Wounds.—Goubaroff of Moscow uses the following treatment for infected wounds. The skin is first painted with iodine, the wound laid open, foreign bodies, etc., extracted and the wound irrigated with isotonic saline solution 1-200 or Dakin's solution. If there is much fetor or gangrene, hot air up to 300° C. is applied (method of Vignat); this resource is seldom necessary. Subsequently hypertonic solution of common salt 8 per cent. or 10 per cent. is used regularly for irrigation. These are well supported, cause no pain, have an intense hemostatic action as well as antiseptic and deodorant properties. The solution also causes the secretion of a flux of lymph which is a favorable *milieu* for leucocytosis. Large gutta percha tubes are used for draining and the wound cavity is now filled with dry gauze or gauze dipped in liquid paraffin. Another good resource is the application of direct solar light or therapeutic rays.—*La Presse Médicale.*

MEDICAL RECORD.

New York, September 23, 1916.

THE MEDICAL RESERVE CORPS OF THE ARMY.

DURING the past few years much has been heard of the need for military and naval preparedness, and it has been pointed out repeatedly that this country is in no sort of a condition to repel a thoroughly organized, well equipped foe with any certainty of success. Especially stress has been laid upon the inadequacy of the Army Medical Department to cope with any untoward situation. It is a fact that the Army Medical Department, the members of which are able and well trained, is woefully inadequate in numbers. Even in times of peace this is evident, and if war were to come, unless matters were considerably bettered in the meantime, infinite trouble would ensue.

The means suggested, and to some extent carried into practice, to provide against this calamity, is to procure surgeons from civil life to supply the deficiency. The Medical Reserve Corps of the army will effect this to a limited extent, but in order to be prepared for war on a large scale the services of civil surgeons must be more largely called upon. However, there is another question of great importance. To be prepared implies being efficient and therefore the members of the Medical Reserve Corps should be so thoroughly trained in their military duties that they may attain at least a fair degree of efficiency.

As First Lieutenant L. D. Frescoln, Medical Reserve Corps, U. S. Army, points out in a paper published in *The Military Surgeon* for August, 1916, the Medical Reserve Corps stands for a body of military surgeons held as an additional force in case of emergency to aid in the same duties as the regular force, having necessarily a working familiarity with the duties of the Medical Corps of the army. Inasmuch as the medical forces connected with the army and navy try to furnish the greatest physical efficiency to the fighting forces, themselves noncombatants, it behooves the reserves in this branch of the service to acquire efficiency themselves along these lines and then instil the same in the combatants.

A medical officer of the army is required to possess knowledge of a wide-reaching and of a somewhat peculiar nature, which is beyond the scope of this article to go over in detail. In particular, however, attention may be drawn to the fact that he must be a more or less expert sanitarian and must be well acquainted with sanitary matters as applied to the army. Unfortunately, Frescoln says, the members of the Medical Reserve Corps generally do not possess sufficient knowledge to warrant them in undertaking military duties, and they are therefore not fitted to take the field as army medical officers. Thus the Army Medical Department may be said to be in a state of unpreparedness.

The happenings in Europe during the past two years and more have afforded a terrible object lesson on unpreparedness and in the case of Great Britain especially on unpreparedness of the Army Medical Department. Great Britain's position in this respect was somewhat analogous to that of this country. She had an army medical corps just adequate for the needs of her small army, and when she was compelled to raise an immense army civil medical practitioners with little or no military training had to be called upon.

Undoubtedly the members of our Medical Reserve Corps have volunteered with the highest patriotic motives, but they should also fully understand that in so doing they have incurred great responsibilities, and that it is their bounden duty to their country and to themselves that they live up to these responsibilties. They should avail themselves of every opportunity for training in the duties of a medical officer, in order that in case of war they may serve their country with efficiency. This is true preparedness.

MILK GRADING.

THE physician is particularly interested in the quality and safety of milk, because it forms the largest, and often the sole, food element of his commonest patient, the child. The quality, the solid content, of the milk is of lesser importance, except that if it is not of some degree of uniformity the calculation in respect of milk modification will not be accurate. Often that is a very important consideration. But the chief thing of interest to the physician is the disease factor in milk. Of all foods, it is the one most likely to carry infection, because it is itself such an excellent medium for the development and for the growth of pathogenic organisms. Wherever there is an opportunity for the initial introduction of even a slight amount of infection into the milk, the probability of these bacteria multiplying, especially when improperly maintained at a temperature conducive to the incubation, is very large indeed. The variety of pathogenic bacteria carried and maintained in milk covers nearly the entire gamut of bacteria. They include especially the tubercle bacillus, the typhoid bacillus, the Klebs-Loeffler bacillus, and the organisms causing scarlet fever, septic sore throat, and other infections.

About 50 per cent of all tuberculosis present in children is believed to be bovine in origin, and coming from the cow's udder; milk is a greater factor in typhoidal infection than water, because it affords a better pabulum for the Eberth bacillus,

and because in water the bacillus becomes attenuated by exposure in a poor medium, and reaches the consumer in a very diluted form. Because of the wide distribution of the milk, any infection must reach a great many, yet the limits of such infections can nearly always be definitely determined by those using the particular supply infected, provided milk from good and bad dairies is not indiscriminately mixed.

The aim and the problem with respect to the milk supply is to raise the quality of all the milk. This is a reform which, because of the very magnitude of the problem, cannot be accomplished at once, but gradually only, through the education of the public to the dangers of unwholesome milk. There should be a demand for higher grade milk at higher prices. The cost of handling milk in properly equipped and properly maintained dairies is higher than in carelessly maintained ones. Various communities have already established compulsory requirements in the handling of milk products with respect to equipment, handling, health of cows, the tuberculin test for the herd, bacterial count, and the temperature at which the milk is maintained. When all milk products—butter, cream, and cheese—are embraced in all these requirements, the ideal will nearly have been reached. The one-grade milk or milk product should be discouraged, since it does not lead to better handling and higher standards.

Perhaps the most forward step in the movement for better and safer milk is the certified milk movement, wherein the index of quality is based on the very lowest bacterial count, carried out in laboratories maintaining uniform bacteriological technique. The height of the whole bacterial content is in proportion to the height of the pathogenic bacterial content. Besides, the bacterial count is the best index of the amount of foreign, extraneous matter introduced into the milk. Milk handled with the least amount of care naturally has the most dirt, the highest bacterial content, and is of the greatest danger. But even the very best milk will always be a source of danger if it is not immediately cooled to a proper temperature and not allowed to rise above this temperature until it reaches the consumer.

For infants who depend almost entirely on milk for their food supply the milk problem during the summer months is a double one, unless the milk is of the highest quality. The heat-exhausted infants are better targets for the bacteria in the milk than during cooler seasons of the year; and the boiling of bad milk does not solve the problem, since spore-forming organisms are not killed by boiling, and, particularly, because boiled milk has not the food quality of raw or pasteurized milk. While pasteurization kills most of the few pathogenic organisms contained in good milk, it is generally believed not to destroy the food quality, although this has been disputed. It is quite certain, however, that the tendency to general malnutrition and even rickets is enhanced by feeding boiled milk over a long period. At any rate, where it is not possible to get the higher grade milk it is better to run the risk of malnutrition than of the many infections caused by bad, mishandled, and generally low-grade milk.

LEECHES IN THE LARYNX.

It is said that Hippocrates mentioned the leech as an occasional cause of blood spitting and writers on foreign bodies in the air passages have often included the leech among the parasites found at times therein. Nevertheless, it is very seldom that a modern laryngologist has an opportunity to see these cases, although they are by no means rare in parts of Spain, Portugal, Italy, and North Africa. The leech often enters the mouths of those who drink certain nonpotable waters, especially when there is no knowledge of the dangers involved. The victims may drink directly from wells, pools, ditches, etc., or water which is fetched and allowed to stand in dirty earthen jugs with narrow necks. The victim drinks from these with no opportunity to see the contents. The victims often know when they have swallowed leeches and apply first aid in the shape of tobacco smoke, vinegar gargles, etc. If the leech does not come away the local practitioner is sought. The nasal fossæ, nasopharynx, pharynx, larynx, trachea, or bronchi may shelter the creature. In some cases considerable tolerance is shown, while in others the picture of incessant cough, strangulation, and hemoptysis, with secondary anemia, demands immediate relief. Violent coughing sometimes expels the creature. When the symptoms are of some duration tuberculosis is readily simulated. The small punctures made by the leech do not pour out blood, but the latter is said to be forcibly sucked into its body and expelled at the caudal end.

Silverio Hernandez contributed an article on this subject to the *Revista Ibero-Americana de Ciencias Medicas* for July. The author relates a personal case, in which the leech had been in the throat for twelve days. The victim had drunk from a narrow-necked earthen jar. Since then he had suffered from dyspneic paroxysms, incessant cough, and hemoptysis. When he could expel large quantities of blood he felt some relief. There was constant and severe distress in the larynx. The nasal chambers and nasopharynx were empty. The laryngoscopic picture, however, could not have been more alarming. To facilitate exploration the throat was cocainized. The epiglottis and arytenoids were congested and much swollen, but the author could perceive a portion of the leech beneath. While an assistant drew forward the epiglottis the author by means of forceps grasped the buccal end of the leech and made traction in the anteroposterior direction. He was fortunate in extracting it at the first attempt. Since this experience the author has acted in five similar cases.

In 1910 Gallegos of Seville reported 112 cases of leeches in the air-passages seen by him in ten years. Of this number 84 involved the larynx. It should be stated that in Andalusia this leech danger is more in evidence than elsewhere in Spain, far more so than in Madrid. Reference to some American standard works shows almost no allusion to this subject, although leeches must be common enough in certain kinds of water which are also, no doubt, used for emergency thirst-quenching. The reason for this is probably that the local leeches, as they are commonly met with in this country, are much too large to enter the rima glottidis readily, and if taken in at all would be swallowed.

PURE AIR AND AIR IN MOTION.

VIEWS with regard to the physiological action of atmospheric conditions have changed considerably in recent years. It was formerly thought man needed pure air, that is to say, air containing but a small proportion of carbon dioxide and organic matter and a due amount of oxygen, but nowadays any kind of air seems to be acceptable if only it is kept stirred up.

Frederic S. Lee read a paper by invitation before the American Pediatric Society on May 8, 1916, in which he said that the most potent of the atmospheric agencies is undoubtedly temperature, but high temperatures exert greater effects when they are accompanied by great humidity. When an existing external temperature is fairly comfortable to the individual an elevation of it, especially when such elevation is accompanied by an increase of humidity, causes distress, and the disagreeable effects are more pronounced when the air is stagnant. Such effects may be modified if the air next the skin be put into motion, but an effective antidote is a reduction in the temperature of the air and this may be assisted by a reduction in its humidity. All experimentation and observation go to demonstrate that a moderately cool and moderately dry air in motion constitutes the most physiologically helpful aerial envelope of the body. Lee holds that artificial ventilating systems should not necessarily be condemned, but should be operated intelligently and may advantageously be combined with window ventilation. As to the merits of what is termed "fresh air," it should be pointed out that the freshness of so-called fresh air lies, not in more oxygen, less carbon dioxide, less organic matter of respiratory origin, and the hypothetical presence of a hypothetically stimulating ozone, but rather in a low temperature, a low humidity, and motion.

Leonard Hill was the first, or one of the first, to demonstrate that the harmful properties of stagnant air, containing a comparatively large amount of carbon dioxide (in the most greatly vitiated air the quantity of carbon dioxide, he claims, is very small) had been immensely exaggerated. The deleterious effects of the air in a closed room lie more in its stagnancy than in any injurious matter it may contain. Keep the air in motion, say these new theorists, and it will be comfortable and to a large extent harmless.

THE AVOIDANCE OF INDUSTRIAL DISEASES.

THE slogan "safety first" should be extended from its original application as a safeguard against accidents to safeguard against disease. There is for instance a tremendous economic loss going on yearly which might be largely prevented by hygienic measures. Dr. Schereschewsky in a recent Public Health Report has outlined a plan for the prevention of industrial diseases which is worthy of note. Estimating that there are from 25 to 30 million industrial workers in the United States and that each one loses from eight to nine days' work a year from illness, that would make the annual loss 600,000 years, or an economic loss of $360,000,000, supposing the workman's average pay was $50 a month. A great part of this loss is undoubtedly preventable and Schereschewsky calls attention to several ways to prevent it. He believes that more attention should be given in medical schools to the interrelations of occupation and disease—in fact he would give a chair to this subject. Death certificates, too, should be filled out with greater exactness and should indicate correctly and exactly the occupation of the decedent. Also information regarding industrial hygiene should be disseminated as industriously as crusades against tuberculosis and alcohol are being carried on now. He suggests six main parts of such an educational campaign: permanent exhibits, popular lectures, bulletins, popular articles in the lay press, and instruction in the public schools. In a great many cases investigated among industrial workers it has been found that disease has been the result of neglect of personal hygiene rather than from inattention to any sanitary precautions connected with the particular occupation. These fundamentals of hygiene should of course be taught in the home and, that failing, in the schools, but it does not seem that the instruction there has hitherto been sufficiently convincing to bear much fruit. When we consider that about one-third of our school children later become industrial workers the importance of including personal hygiene in every public school curriculum becomes evident.

A YANKEE TRICK IN ENGLAND.

THERE has come to our notice recently a description of a bit of commercial shrewdness which is of the kind commonly spoken of as "Yankee" although the scene is laid in the lanes of the Old England, instead of the New. It is not known whether or not the enterprising individual in question was English, but the whole thing sounds very much like one of the amazing tales with which Sam Weller regaled the ears of Mr. Pickwick. It seems that every autumn a man used to bring to a large wholesale drug house in London a quantity of hemlock seed which he sold at half the market price. Finally, says *Garden* in a recent issue, the curiosity of one of the members of the firm became aroused and he asked the man how he could afford to sell the drug so cheaply. The stranger was loath to tell at first, but after being promised that nothing would be done to interfere with his business, he described his method. Every spring he filled his pockets with the seed and went out into the country. Wherever he saw a good, wide hedgerow he sowed the seed broadcast. Then he went his way and worried no more over his crop until the fall when he revisited the scene of his labors. He would then call the farmer's attention to the "weeds" in his hedge, offering to cut them down for a shilling a hedge, an offer which the farmer gladly accepted. Thus was the ground furnished free and he was paid to cut the harvest. In view of the great shortage in drugs owing to the war a few such ingenious minds should be turned to the question of domestic drug-raising, not necessarily on some one else's land, but at least on United States land.

DIABETES MELLITUS IN JAPAN.

ACCORDING to various contemporary authorities diabetes runs a mild course in Japan and seldom leads to coma. Polyuria is absent throughout, and with it the symptoms which announce the onset of the disease. This behavior is the more singular because of the preeminently carbohydrate diet of those people. Where the disease is most severe,

on the other hand, the people are meat-eaters. Le Goff, whose researches into this subject were recently presented before the French Academy of Sciences (*Gazette hebdom. des sciences médicales de Bordeaux*, July 8) tested both healthy and diabetic Japanese for carbohydrate tolerance and found a better utilization of sugar in comparison with other races. It is not made clear to the reader why the benign diabetes of the Japanese cannot straightway be termed a glycosuria.

News of the Week

Poliomyelitis Epidemic Continues.—The decrease in the number of cases of poliomyelitis during the past week was not so great as had been hoped for, 254 being recorded up to September 16, as against 352 for the preceding week. The total number of cases to that date was 8,731, with 2,172 deaths. Because of this continuance of the disease, the United States Public Health Service decided that it would be unwise to discontinue its work of inspection of travel, which will, therefore, be carried on for an indefinite time, or as long as present conditions prevail. The theory that the disease is conveyed by rat fleas has been advanced, and is being studied in several laboratories. Fifty monkeys, to be used in studying infantile paralysis, were shipped last week from San Francisco to the Rockefeller Institute. They are the survivors of a shipment of 100 received in San Francisco from the Orient a few days before. Mr. Nathan Straus has called attention to the record of the Straus milk depots in New York, as suggesting the theory that infantile paralysis may be carried by milk. It is stated that not a single case of the disease occurred among the 2,500 children who received pasteurized milk from the milk stations. As good a guess as any is that the disease is due to a protozoan parasite, with an exogenous cycle in the mosquito, or some other invertebrate host, which is active in hot weather, and becomes more torpid during the cool spells, following which there is usually a temporary decrease in the morbidity rate. For breaking the quarantine regulations imposed by the Board of Health, because of the occurrence of a case of poliomyelitis in his family, a citizen of Long Island City was fined $5 in the Long Island City Police Court on September 14. The total number of cases in New York State outside of New York City to September 16, was 2,865, with 302 deaths. In New Jersey, up to the same date, 3,390 cases had occurred.

Some Practical Notes on Blood Pressure.—In the legend of Hemobarogram No. 5, in the article with the above title, published in the issue of September 16 (page 490), the word typical should have been atypical.

Sir Thomas Lauder Brunton of London died on Saturday of last week at the age of 72 years. He was widely known as a graceful writer on medical subjects, especially therapeutics. He was an M.D. of the Royal University of Ireland, LL.D. of the University of Edinburgh, a fellow of the Royal College of Physicians, and of the Royal Society of Medicine, of which he was also vice-president. He was knighted in 1900 and made a baronet in 1908.

Lectures at Yale.—The Silliman lectures for 1916 of Yale University will be given by Prof. J. S. Haldane, LL.D., F.R.S., on October 9, 10, 12, and 13, at the Lampson Lyceum, New Haven. Prof. Haldane's title will be: "Organism and Environment as Illustrated by the Physiology of Breathing."

New Psychopathic Hospital.—The directors of the Bureau of Social Hygiene, and the Board of Managers of the New York State Reformatory for Women, announce the opening on September 16, of the Psychopathic Hospital of the Laboratory of Social Hygiene at Bedford Hills.

The Wellcome Prizes.—The Henry S. Wellcome prizes, offered through the Association of Military Surgeons, and open for competition to all present and former medical officers of the Army, the Navy, the Public Health Service, the organized militia, United States volunteers, the Medical Reserve Corps of the Army and Navy, and the Officers' Reserve Corps of the United States Army, will not be awarded until after December 15, 1916, the council of the association having voted to extend the time of entry for competing essays to that date. This has been done because of the large number of members now on duty with the troops at the border. Two prizes are offered, the first, a gold medal and $300, and the second, a silver medal and $200. The subject for the first prize is: "The most practicable plan for the organization, training, and utilization of the medical officers of the Medical Reserve Corps, United States Army and Navy, and of the medical officers of the Officers' Reserve Corps, United States Army, in peace and war." For the second prize the subject is: "The influence of the European war on the transmission of the infectious diseases, with special reference to its effect upon disease conditions of the United States." The essays (five copies signed by a nom de plume), not to exceed 20,000 words exclusive of tables, must be addressed to the secretary of the Association of Military Surgeons, United States Army Medical Museum, Washington, D. C.

Murphy Field Hospital Disbanded.—In consequence of the death of Dr. John B. Murphy, the field hospital organized by him as the Chicago medical unit, and forming a part of the general field hospital of the British expeditionary force in France, has been disbanded. The unit had the distinction of winning the royal Red Cross medal, and of being twice mentioned in dispatches for effective work.

Sick Rate Among Troops.—The health of the New York division of the National Guard on duty in Texas was reported recently to have been slightly better during August than during July, notwithstanding the epidemic of paratyphoid, the respective percentages being given as 1.52 and 1.57. There were during August about 19,000 New York troops on duty near the border. The highest daily rate of illness during the month was 2.76 per cent. There has been a marked decrease in the number of cases of paratyphoid.

Gifts to Charities.—The $2,500 presented to New Jersey charities by President Wilson when rental for Shadow Lawn, his summer residence, was refused by the owner, has been divided among eight institutions, including the following: $500 each to the Monmouth Memorial Hospital, Long Branch, the Ann May Hospital, Spring Lake, and the Paul Kimball Memorial Hospital, Lakewood; $200 to the Methodist Episcopal Home for the Aged, Ocean Grove, and $100 each to the Home for the Aged, Asbury Park, and the Long Branch Visiting Nurses' Association.

By the will of the late Alice E. Lathrop, of Hartford, Conn., the Hartford Hospital receives a bequest of $2,500.

Tuberculosis in War Camp.—The Canadian Military Hospital Commission is investigating the conditions in the military camps of the Dominion as regards the incidence of tuberculosis. It is stated that the proportion of soldier's tuberculosis has been larger in the military camps than at the front.

Adopts Physical Training Program.—The New York State Board of Regents has given unanimous approval to the program for physical training as recommended by the State Military Training Commission. The program, which is intended for the use of every school in the State, calls for a minimum of twenty minutes a day to be devoted to physical exercise, and is said to be the most comprehensive plan for health education and physical training ever adopted by a State.

Physicians Licensed.—As a result of the recent examinations for admission to practise medicine in the State of Maine, certificates were granted to nine physicians. Twelve candidates took the examinations. In addition, three physicians were granted certificates without examination through reciprocity with other States.

Personals.—Dr. Hermann F. Biggs, Commissioner of Health of the State of New York, was operated upon at St. Mary's Hospital, Rochester, Minn., on September 13, for chronic appendicitis and gallstones. The operation was successful and Dr. Biggs is reported to be on the road to rapid recovery.

Reports from Paris tell of the illness of Dr. Joseph A. Blake, as a result of the strenuous work he has been doing among the wounded in his hospital in that city.

Dr. John B. MacDonald has been appointed superintendent of the Danvers State Hospital, Danvers, Mass., succeeding Dr. George M. Kline, who was recently made chairman of the newly-created State Commission on Mental Diseases. Dr. MacDonald has for a time been assistant superintendent at the hospital.

To Head Lunacy Board.—Dr. Charles W. Pilgrim, superintendent of the Hudson River State Hospital, Poughkeepsie, N. Y., has been appointed by Governor Whitman to serve as president of the New York State Lunacy Board. Dr. James V. May, former head of the board, resigned some time ago to accept a similar position in the State of Massachusetts. Dr. Pilgrim served as president of the board also in 1906-07, having been appointed at that time by Governor Higgins. The salary of the position is $9,000 a year.

Plagues in Mexico.—An apparent increase in both typhus fever and yellow fever is reported in official dispatches from Mexico. The diseases are prevalent especially in the coast ports, and the quarantine authorities are keeping a close watch on the situation.

Hospital Needs Funds.—The New York Ophthalmic Hospital, it is announced, may shortly be compelled to close its doors because of lack of funds, a marked falling off in subscriptions having occurred since the beginning of the war. Two of the free clinics for children have already been closed, and it is feared that it will be necessary still further to curtail the work.

Medical Colleges to Open.—The College of Physicians and Surgeons, Columbia University, New York, will open on September 27 the decline in the epidemic of poliomyelitis making unnecessary the postponement of the opening date.

The Long Island College Hospital, Brooklyn, N. Y., will begin the session of 1916-17 on September 25. The college courses given by Columbia University at the Long Island College Hospital will open on September 28.

The British Medical Association.—The annual representatives' meeting of the British Medical Association was held on July 28 and 29, and transacted the routine business, no scientific meetings being held. Mr. E. B. Turner of London was re-elected chairman of representative meetings, 1916-17, and Mr. T. W. H. Garstang of Altrincham, deputy-chairman. Sir Thomas Clifford Allbutt, K.C.B., LL.D., was elected president of the Association, 1916-17. A resolution was also passed congratulating Sir Clifford Allbutt on the attainment of his 80th birthday. Dr. G. E. Haslip of London, was elected treasurer of the Association for the period 1916-19.

Dover (N. H.) Medical Society.—At the annual meeting held in Rochester on September 8, the following officers were elected for the ensuing year: *President*, Dr. Thomas J. Morrison, Somersworth; *Vice-President*, Dr. John H. Bates, East Rochester; *Secretary-Treasurer*, Dr. Roland J. Bennett.

Teaching Hygiene to School Children.—A system of health care and instruction in hygiene is to be introduced into the New York City schools this fall under the direction of Dr. C. Ward Crampton, director of the department of physical training, hygiene, and athletics of the public schools. A program of hygienic events of the day has been prepared, including directions as to bathing, mouth hygiene, care in eating, exercise, etc., and in the school children are to be placed in seats suited to them, the matters of ventilation and temperature are to be carefully attended to, and pupils are to be organized in squads whose duties will be to care for order and cleanliness in the schoolroom, building, and neighborhood. All pupils are to have their eyes tested, and the parents will be supplied with copies of a pamphlet on "How to Safeguard the Health of the Child."

The Legality of Pay Clinics.—In response to a request of the Medico-Economic League, the office of the Attorney General of the State of New York has recently given the opinion that it is lawful for a dispensary which is conducted in compliance with the standards, requirements, and purposes of Section 291 of the State Charities Law, to make a charge of one dollar per visit. Whether a person who pays one dollar for treatment at such a dispensary, is a fit object for charity depends, the opinion states, entirely upon the circumstances in the individual case. If all that the patient can afford to pay is one dollar, and he can obtain treatment by a specialist at a dispensary for that amount, while treatment by the same specialist elsewhere would be beyond his means, there is no reason why he should not avail himself of the opportunity. Since Section 296 of the State Charities Law provides that "Any person who obtains medical or surgical treatment on false representations from any dispensary licensed under the provisions of this article shall be guilty of a misdemeanor and on conviction thereof shall be punished by a fine of not less than ten dollars and not more than two hundred and fifty dollars," there seems

no reason to fear that the dispensaries will be abused by persons who can afford to pay the full quota for specialized surgical or medical treatment. In the opinion of the Attorney General's office, the establishment of dispensaries of the standard conducted by such institutions at Mt. Sinai Hospital and others, should be encouraged and assisted, rather than hampered and hindered.

Obituary Notes.—Dr. ENRIQUE NUÑEZ, secretary of sanitation for the Republic of Cuba, died on September 16 in the Presbyterian Hospital, New York, after a few days' illness from infection following a cut on his foot. Dr. Nuñez was graduated from the University of Havana in 1886, and received his doctor's degree from the same institution in 1893. For many years he had been one of the most prominent physicians in Cuba. He was in his forty-fifth year.

Dr. JAMES R. CANNON of Irvington-on-Hudson, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1903, visiting surgeon to the Tarrytown Hospital, and a member of the Society of the Alumni of St. Luke's Hospital and the Alumni of Sloane Hospital for Women, died suddenly at Walker, Minn., on September 5.

Dr. EUGENE POTTER STONE of New York, a graduate of the Medical School of Harvard University, Boston, in 1884, medical director in the United States Navy, retired, and a member of the American Medical Association and the New York State and County Medical Societies, died suddenly, at North Sutton, N. H., on September 5, aged 55 years.

Dr. SOLOMON BARUCH of New York, a graduate of the New York Homeopathic Medical College and Flower Hospital, New York, in 1876, died at his home, from arteriosclerosis, on September 6, aged 60 years.

Dr. JOSEPH SAMUEL CHAGNON of Willimantic, Conn., a graduate of Victoria University, Medical Department, Toronto, in 1883, died at his home, from edema of the lungs, on August 29, aged 57 years.

Obituary.

ADONIRAM BROWN JUDSON, M.D.,

NEW YORK.

DR. A. B. JUDSON, one of the first generation of orthopedic surgeons in this country, died of diabetes at his home in New York City, on Wednesday of this week. He was born in Burma, where his father long lived as a Baptist missionary, in 1837. After graduating in arts from Brown University, he studied medicine at the Jefferson Medical College, from which he was graduated in 1865. Before graduation he served as assistant surgeon in the Civil War. After coming to New York he took a course at the College of Physicians and Surgeons, where he obtained a second degree of M.D. in 1868. He was a fellow of the American College of Surgeons, of the New York Academy of Medicine, and of the American Medical Association, and a member of the New York State and County Medical Societies, and the New York Pathological Society, and ex-president of the American Orthopedic Association. During his period of active practice Dr. Judson wrote many journal articles and some books, and even after retirement he retained a keen interest in his profession and continued to contribute to its literature, having published a brief article in these columns as late as January of the present year.

TREATMENT OF CONVALESCENT SOLDIERS—COMMAND DEPOTS—LIGHT DUTIES ON LINES OF COMMUNICATION—BALNEOLOGY—COMPRESSED AIR—TRAINING OF MUSCLES AND JOINTS.

LONDON, August 26, 1916.

THE treatment of convalescent soldiers by physical means has been discussed at the Royal Society of Medicine *a propos* of a paper by Major Tait McKenzie, R.A.M.C. He compared a great military hospital to a general post office as the sick and wounded are, as it were, sorted out in several classes. Cases that may be called first-class matter are at once on reception distributed to the regular hospitals, either Red Cross or military, when after a short course of treatment by operation or otherwise they may be able to return to the front. Second-class matter is composed of cases requiring a stay at a convalescent hospital where they can receive a longer course of treatment by an officer of the R.A.M.C. A large number of these patients eventually find their way back to the front. The third class comprises cases difficult to deal with as they are too tedious for hospitals or convalescent camps. Early in the war they were passed from one depot to another without giving satisfaction to any of the medical officers under whom they spent short periods. Last autumn the director-general arranged a series "command depots," under a combatant officer for discipline and general management. A medical officer was attached to each. To these depots were sent to all patients as to whom there was a reasonable prospect of recovery within five or six months. From there it was hoped to return every available man to service; those only fit for light service abroad might replace others in light duties on lines of communication and release others for more active service. So others again from whom no further service could be expected might be discharged from the army.

With the help of the society's committee on Balneology the ordinary hut was converted into an ideal hydrothertherapeutic establishment. The hot and cold douche had both rendered good service in treatment and also proved useful in diagnosis—especially in cases of suspected rheumatic origin. Serious cases of rheumatism were treated by a daily tub bath, of 15 to 20 minutes duration, at a temperature of 98 F., followed by general massage. The pool bath was kept at 94 F. and would hold twelve men sitting up to their necks on in the water. In it they staid an hour. This was the practice in all cases of shock with disordered cardiac action. The whirlpool bath was used for limbs with painful scars or frost-bitten, the water being kept at 110° F. and violently agitated. Compressed air introduced into the stream provided bubbling, effervescent envelope for the painful limb.

After twenty minutes of this immersion the part would be flushed, but the patient would express himself as comfortable and the circulation would be accelerated and remain so for hours. This is a good preparation for massage and other manipulations which often cannot be borne without it. When a sodden scar is undesirable dry heat should be used. Zander machines for passive movements are complicated and far too expensive. Following manipulations the muscles and joints require systematic

re-education by tasks of progressively increasing difficulties and in time a patient should be thrown more on his own resources and made to practice free gymnastics without the help of machine or operator. At this stage men suffering from shell shock or debilitated in any way may begin the exercises and gradually increase them up to the stage of nearly but not quite full training. A pulse which by faradism, baths, and rest had been reduced to 80 would mount up again to 120 or even 140 on attempting anything arduous. The command depots have given results which must be satisfactory to the director-general, for half the cases have been rendered fit to return to active service and have rejoined their units in the fighting line, 12 per cent. have been sent to lines of communication abroad, 12 per cent. to useful sedentary work at home, the residue of 28 per cent. being discharged as permanently unfit. These command depots, since their establishment seven months ago, have returned a full Army Division to the fighting line.

OUR LETTER FROM ALASKA.

(From Our Special Correspondent.)

ALASKANITIS ENDEMIC IN NORTHWESTERN ALASKA.

St. Michael, July 31, 1916.

To many readers this will be an unfamiliar term, but to persons who have passed at least one closed season in northern or northwestern Alaska the word "Alaskanitis" will remind them of many instances that have come under their observation.

Just as with general paresis, this condition seems to be more prevalent in the better class, the words "better class" in this sense meaning the white people in contradistinction to the native Eskimo or Indian, who seems immune. The condition probably prevails all over northern and northwestern Alaska, at least where white people have settled. It affects both sexes alike, and no age seems exempt. Although the condition is endemic with sporadic cases occurring the year around, it reaches an epidemic form after the close of navigation when Alaska is shut off from the outside world. The number of cases increases progressively from February to June and by this time all the white population has become more or less affected. Persons new in the country seem particularly prone to "Alaskanitis," but prolonged residence does not establish absolute immunity as the writer has seen a person forty-four years in the country have it in an acute form.

Now what is "Alaskanitis?" I don't know, but a description will be based upon the outward manifestations. As above said, "Alaskanitis" prevails after the close of navigation, that is when no new faces are to be seen. The various communities are but sparsely settled, necessitating the same faces to meet many times a day. Should you go to the store you meet the same faces; should you go to the post office, skiing, snow-shoeing, mushing, calling, or what not, the same faces are there, and, worst of all, there are no other faces. The outside world is cut off; there is no news, the days become progressively shorter and shorter until but three or four hours of light remain. The nights grow longer and longer until about twenty hours out of the twenty-four are consumed with the quietude and mystery of darkness almost continually hovering over you. You hear almost daily others' experiences of last summer and relate yours; the experiences of summer before last are also told, even experiences dating back to early childhood are in like manner related without the slightest emotion, humor, or wit. After a few months of these experiences one hesitates to meet another, knowing what will be related, so one seeks more or less solitude, but this, too, becomes tiresome. At this stage, you have become sensitized or highly susceptible to "Alaskanitis." About this time some one will start gossiping and with lightning-like rapidity you will grasp this piece of "news"—being the first in a long time—and with such additions and subtractions as seem necessary to make the story more interesting it passes from one to another. Finally the story reaches the originator, who does not even recognize it as his story, so there are two stories in the field. This will cause sociological segregation and retaliating stories will start. As the majority of the population is made up of persons about whom you may readily believe reports of questionable nature, divisions and subdivisions occur, until by June, or the opening of navigation, each person may represent a society of his own.

With the opening of navigation there is a great influx of new faces; gold seekers, tourists, and others come into the country by the hundreds. The bright, warm, sunshiny days with the wind in the right direction soon drive out the ice, and ships appear bringing news, new faces, new associates. The Sourdough's (a white person who has been in Alaska more than one year) troubles are forgotten and the condition of his mind that seemed chronic now disappears, only to relapse, however, during the coming fall or winter. This is "Alaskanitis" in a typical form and is more conducive to discontent during the long winters than probably all other elements combined which enter into the life spent in this part of the world.

"Alaskanitis" differs from "Philippinitis" in not presenting in so marked a degree the symptoms of nostalgia.

3. Circulatory Disturbances in the Obese.—Clifton L. Buck says that beneficent results have been noted as a result of the method he uses in preventing the first signs of cardiac weakness in the slightly obese; in all cases suffering from diseases entailing an increased burden upon the circulatory system, and in the cases of extreme obesity. He believes that this is a particularly good field for prophylaxis and that it should be considered one of the most important duties of the family physician to prevent the development of obesity in all cases in which he recognizes cardiac weakness, as for instance, valvular trouble developing from some of the acute infections of childhood, and in families which show an hereditary tendency toward obesity. In severe cases with edema absolute rest is insisted upon for two or three weeks or longer. Digitalis or tincture of opium may be used as indicated. The diet at first should consist of skim-milk, cooked fruits, and eggs. When the condition has improved the diet may be in-
